A NOTE TO THE READER

THE ARGUMENT

This book is what would conventionally be called a single argument. That is why I have chosen not to publish it as three separate books: one on neuropsychology – how our brains shape reality; one on epistemology – how we can come to know anything at all; and one on metaphysics – the nature of what we find in the cosmos. It is intended as a single whole, each part illuminating, and in turn illumined by, the others.

And yet it is also not an argument, in the conventional sense, at all. If we want others to understand the beauty of a landscape with which they may be unfamiliar, an argument is pointless: instead we must take them there and explore it with them, walking on the hills and mountains, pausing as new vantage points continually open around us, allowing our companions to experience it for themselves.

Such, at any rate, is my intention in this book. The journey matters – because it *is* the arrival. This means that while, for some, every succeeding view will disclose some new aspect of an always changing landscape with which at every turn they become better acquainted, for others the landscape will appear to be, unrewardingly, always the same landscape.

Importantly, this also means that the reader must *not* feel that the whole book has either to be read in its entirety or not at all. Continuing the analogy of a journey, it can be taken in (I hope) enjoyable stages; and can be put down and picked up, or explored according to whim. My hope is that my reader will end by reading much of it anyway, but do so in a spirit of an intellectual friendship, not as another challenge to fit in to a busy life.

At one point I was going to call this book *There Are No Things*. I changed my mind when I saw that it might align me with a nihilistic trend in post-modernism that I deplore. It also gave the impression that I was arguing for ‘truth-as-correctness’ rather than ‘truth-as-unconcealing’. My aim is to clear away the assumptions that cloud our vision: and the assumption of a materialist world composed of ‘things’ is the greatest impediment we face. In an obvious sense, there are things: my hope is that the reader will not abandon them, but reconceive them in a richer way. In summary, my trust is in my readers, that for them something deeper will be

unconcealed, and that they will literally *dis*-cover a new vision of the world for themselves.

REFERENCES

I apologise for the number of references. If I were merely relaying the conventional dogmas of neuroscience, they would hardly be necessary: but I am not, and so they are. I very much hope that this book, large as it is, will be read by the widest possible audience of intelligent general readers. I have therefore taken care that no specialist knowledge is assumed. At the same time, I aim to make a modest, but I hope significant, contribution to neuroscience. This makes the presentation of a very large body of research evidence inevitable; that should not deter the non-specialist reader, who may feel free to pass over the detail, mainly contained in notes as far as possible next to the text to which they refer. For colleagues, I have tried to make references as easy as possible to track down. It can be frustrating to be referred (as now seems to be the norm) to a volume of a journal without being directed to the part, leaving one to guess which of, perhaps, 12 such parts to access; I have tried always to give the full necessary information, and, to save the reader's time, to indicate precise pages, where relevant, within a larger work. I have saved space by removing the conventionally supplied city in which a book is published: to know that Oxford University Press is based in 'Oxford, UK' is hardly a revelation, and in today's world where a publisher claims to be based is largely irrelevant.

TRANSLATIONS

In the book there are many translated passages, sometimes from sources that have not been translated, or might have been better translated, into English. In this I hope to have made a small contribution to future scholarship in the area. Unless the reader is referred in the notes to a particular English translation as the source, all translations may be assumed to be by myself. To avoid repetition, I have omitted reminders of this fact. Where possible, if using another's translation, I have consulted the original; and where I rely on my own translation, I have generally given the original, so that those more adept than I can judge for themselves.

The problem of neurology is to understand man himself.

—*Wilder Penfield* ¹

ἡμεῖς δέ – τίνες δὲ ἡμεῖς;
But we – who *are* we?

—*Plotinus* ²

INTRODUCTION

Yes, a key can lie for ever in the place where the locksmith left it,
and never be used to open the lock the master forged it for.

—Ludwig Wittgenstein [1](#)

This book is an attempt to convey a way of looking at the world quite different from the one that has largely dominated the West for at least three hundred and fifty years – some would say as long as two thousand years. I believe we have systematically misunderstood the nature of reality, and chosen to ignore, or silence, the minority of voices that have intuited as much and consistently maintained that this is the case. Now we have reached the point where there is an urgent need to transform both how we think of the world and what we make of ourselves; attempting to convey such a richer insight is the ambition of this book.

We have been seriously misled, I believe, because we have depended on that aspect of our brains that is most adept at manipulating the world in order to bend it to our purposes. The brain is, importantly, divided into two hemispheres: you could say, to sum up a vastly complex matter in a phrase, that the brain's left hemisphere is designed to help us *ap*-prehend – and thus manipulate – the world; the right hemisphere to *com*-prehend it – see it all for what it is. The problem is that the very brain mechanisms which succeed in simplifying the world so as to subject it to our control militate against a true understanding of it. Meanwhile, compounding the problem, we take the success we have in manipulating it as proof that we understand it. But that

is a logical error: to exert power over something requires us only to know what happens when we pull the levers, press the button, or utter the spell. The fallacy is memorialised in the myth of the sorcerer's apprentice.² It is hardly surprising, therefore, that while we have succeeded in coercing the world to our will to an extent unimaginable even a few generations ago, we have at the same time wrought havoc on that world precisely because we have not understood it.

This book, then, is about the nature of reality. It's about how we are equipped by our brains to try to understand it, and what we can learn from that. It's about the approaches that are available to us to gain an understanding of reality, given that equipment. It attempts, consequently, to give an account of reality that seems truer to the evidence than the one to which we have long been accustomed; one that is far-reaching in its scope, and consistent across the realms of contemporary neurology, philosophy and physics.

And from that follows an account of who *we are*, on which nothing less than our future depends.

What in particular I offer here is a new synthesis of philosophy and science which I believe is importantly, and excitingly, liberating to both parties. As a rule, philosophy and science go on as if the other did not exist. Scientists tend to see philosophy as a luxury they can't afford to get involved with, a ball and chain that will slow them down in their race for the next discovery; philosophers to see science as somewhat beneath them, and in any case irrelevant to the ponderings of the mind on itself. But as the great physicist Erwin Schrödinger put it in *Science & Humanism*,

it seems plain and self-evident, yet it needs to be said: the isolated knowledge obtained by a group of specialists in a narrow field has in itself no value whatsoever, but only in its synthesis with all the rest of knowledge and only inasmuch as it really contributes in this synthesis toward answering the demand, τίνας δὲ ἡμεῖς; 'Who are we?'³

Here Schrödinger is remembering Plotinus, one of the greatest of Greek philosophers; but his point is of a contemporary relevance that it is impossible to overstate.

Seventy years on from Schrödinger's pronouncement, specialisation makes it even harder to expect more than a tiny handful of scientists and philosophers to be in a position to venture into a genuinely new understanding of their (in reality) common enterprise, one that has the potential hugely to enrich both parties. When any attempt is made to reach out a hand across the distancing void, it is almost invariably an exercise in reinforcing the status quo: the scientists telling the philosophers that they find only machinery, and the philosophers reflecting back to the scientists that a mechanistic view is the best option on offer. Since what you find is a product of how you attend, this is a more or less pointless exercise in making sure that both parties sink to the bottom in the shortest possible time.

Philosophy is engaged in weighing evidence so as to decide between conflicting ways of understanding the world, each of which has something to be said for it. This is why philosophy never ends. But what if, among the evidence, there were some way of recognising a particular take on the world as – not just floating in a contextual void, but rather – the predictable result of paying a quite particular kind of attention to the world? And what if we happened to know a great deal about the evolutionary purposes, and the consequences, of such a way of attending, including what weight we should attach to its findings?

And what if such insights, gained from science, and explicated by philosophy, could be applied in turn to the science of mind itself? Then might we not begin to see a fertile symbiosis of philosophy and science, helping one another, each turn building on the next, to rise to a new, more truthful vision of who, indeed, *we are*?

RE-THINKING SOME ASSUMPTIONS

At the core of the contemporary world is the reductionist view that we are – nature is – the earth is – ‘nothing but’ a bundle of senseless particles, pointlessly, helplessly, mindlessly, colliding in a predictable fashion, whose existence is purely material, and whose only value is utility. Neither Plotinus nor Schrödinger would have been impressed. I cannot remember a time when I thought this sounded at all convincing; and a lifetime’s thinking and learning has done nothing to allay my scepticism. Not only is it mistaken, I believe, but actively damaging – physically, to the natural world; and psychologically, morally, and spiritually to ourselves as part of that world. It endangers everything that we should value.

Reductionism can mean a number of things, but here I mean quite simply the outlook that assumes that the only way to understand the nature of anything we experience is by looking at the parts of which it appears to be made, and building up from there. By contrast I believe that the whole is never the same as the sum of its ‘parts’, and that, except in the case of machines, there are in fact no ‘parts’ as such, but that they are an artefact of a certain way of looking at the world. For this reason it is every bit as true that what we call the parts can be understood only by understanding the whole to which they belong. And with the reductionist outlook goes determinism, the belief that if we knew enough about the position and momentum of every particle in the universe we could predict everything that happens from here on in, including your every thought, desire and belief.

Even if contemporary physics did not demonstrate that this is an impossibility, there is a problem with this kind of argument. Reductionists and determinists unerringly fail to take account of the fact that their own arguments apply to themselves. If my beliefs are ‘nothing but’ the mechanical products of a blind system, so are all views, including those of the reductionist. If everything is already determined, the determinist’s tendency to embrace determinism is also merely determined, and we have no reason to take it seriously (since we are all determined either to believe it or not already). As the philosopher Hans Jonas observed, there is an unspoken hierarchical principle involved:

the scientist does take man to be determined by causal laws – but not himself while he assumes and exercises his freedom of enquiry and his openness to reason, evidence and truth. His own working assumptions involve free will, deliberation, and evaluation as aspects of himself, but those qualities and capacities are stripped away from and denied to the human object or thing that he is inspecting... ⁴

If it were not for the fact that this world-picture is mistaken, you might argue that we ought, nonetheless, to ‘man up’ and accept it. But it *is*, as I hope to demonstrate, massively mistaken. My aim is to show the reader the magnitude of the error, and its consequences. I say ‘show’, because I cannot, any more than anyone else, prove anything finally and irrefutably – the material with which we are dealing makes that impossible; but rather I wish to take my reader by degrees to a new vantage point, one built upon science and philosophy, from which, in all likelihood, the view will appear at the same time unfamiliar, and yet in no way alien – indeed rather the opposite. More like a home-coming. From there the reader must, of course, make up his mind for himself.

‘To put the matter in a nutshell’, wrote the philosopher Friedrich Waismann,

a philosophical argument does more and does less than a logical one: less in that it never establishes anything conclusively; more in that, if successful, it is not content to establish just one isolated point of truth, but effects a change in our whole mental outlook so that, as a result of that, myriads of such little points are brought into view or turned out of sight, as the case may be.⁵

Such a whole shift of view, rather than the adjustment of a few points within a familiar landscape, is what I hope for my reader.

And that process must begin with the very idea of *things*. ‘The world is not just a set of separately existing localized objects, externally related only by space and time’, writes Tim Maudlin, Professor of Philosophy and Physics at NYU. ‘Something deeper, and more mysterious, knits together the fabric of the world.’⁶ Indeed, according to Richard Conn Henry,

Professor of Physics and Astronomy at Johns Hopkins, ‘to see the Universe as it really is, we must abandon our tendency to conceptualize observations as things’.⁷

Reductionism envisages a universe of *things* – and simply material things at that. How these things are related is viewed as a secondary matter. However, I suggest that relationships are primary, more foundational than the things related: that the relationships don’t just ‘connect’ pre-existing things, but modify what we mean by the ‘things’, which in turn modify everything else they are in relationship with. That is because what we are dealing with are, ultimately, relations, events, processes; ‘things’ is a useful shorthand for those elements, congealed in the flow of experience, that emerge secondarily from, and attract our attention in, a primary web of interconnexions. I have nothing against things, provided we don’t see them as primary.

In our ordinary way of thinking, things must be established before there can be relationships, and so this about-turn should seem paradoxical; but as I shall explain, paradox very often represents a conflict between the different ‘takes’ afforded by the two hemispheres. However, we must also be prepared to find that, as Niels Bohr recognised, whereas trivial truths manifestly exclude their opposites, the most profound truths do not. This is itself a version of the realisation that what applies at the local level does not necessarily apply in the same way at the global level. The failure to observe this principle underlies some of the current misconceptions of both science and philosophy.

I believe that nowadays we live no longer in the presence of the world, but rather in a re-presentation of it. The significance of that is that the left hemisphere’s task is to ‘re-present’ what first ‘presences’ to the right hemisphere. This re-presentation has all the qualities of a virtual image: an infinitely thin, immobile, fragment of a vast, seamless, living, ever-flowing whole. From a standpoint within the representation, everything is reversed. Instead of seeing what is truly present as primary, and the representation as a necessarily diminished derivative of it, we see reality as merely a special case of our representation – one in which something is added in to ‘animate’ it. In this it is like a ciné film that consists of countless static slices requiring a projector to bring it back into what at least looks to us like a living flow. On the contrary, however, reality is not an animated version of our re-presentation of it, but our re-presentation a devitalised version of

reality. It is the re-presentation that is a special, wholly atypical and imaginary, case of what is truly present, as the filmstrip is of life – the re-presentation is simply what one might call the ‘limit case’ of what is real. Stepping out of this world-picture and into the world, stepping out of suspended animation and back into life, will involve inverting many of our perhaps cherished assumptions.

This concept of the limit case is one I will recur to. I am using it to mean that what is essential to the phenomenon has in this case reached its minimum, without being actually extinguished. It should not be taken as typical, but as the very opposite. Thus, reverting to the example of relationships and the ‘things related’, relationship is the norm; isolation, if it could ever be wholly achieved (which it cannot), would be the limit case of interrelation. Or again, to continue the image of the ciné film: in the Newtonian universe, the natural state of any ‘thing’ is stasis. According to Newtonianism, motion is an aberration from this primal state of perfect inertia, requiring the equivalent of the projector (some energy conceived as *added from outside*) to set it going. However, nothing we know is in reality ever entirely static; and relative stasis, not motion, is the unusual circumstance that requires explanation. Stasis is, in other words, the limit case of motion, in which it approaches, but never completely reaches, zero. Motion, then, is not an unusual departure from stasis, but stasis an unachievable imaginary state, which in reality can be approached only as an asymptote.

Let me give a few further examples, which I grant may seem at first sight surprising, even nonsensical. We could start with our own thought processes and their expression in language. The explicit is not more fully real than the implicit. It is merely the limit case of the implicit, with much of its vital meaning sheared off: narrowed down and ‘finalised’. The literal is not more real than the metaphorical: it is merely the limit case of the metaphorical, in which the wealth of meaning is collapsed into a 1:1 correspondence for a useful, temporary, purpose.

More importantly, it’s the wider cosmos whose deep structure we are inclined to misunderstand. It may seem obvious that randomness is the primary condition and that order is an unusual phenomenon that emerges from (how?), and is supervenient on, that primary chaos. However, order is not a special case of randomness, but randomness merely the limit case of

order, which is the universal norm. Indeed, true randomness is a theoretical construct that does not exist.

Complexity and simplicity are relative terms. However, complexity is surely, we imagine, a more unusual state of affairs arising out of the agglomeration of more simple elements – isn't it? I believe that this is a mistake – one all too understandable, given our world view, but a mistake nonetheless. Rather, complexity is the norm, and simplicity represents a special case of complexity, achieved by cleaving off and disregarding almost all of the vast reality that surrounds whatever it is we are for the moment modelling as simple (simplicity is a feature of our model, not of the reality that is modelled). In keeping with this – and, don't worry, right now this *should* seem crazy – inanimacy is better regarded as the limit case of animacy, something I will come to later in the book.

Potential is not simply all the things that never happened, a ghostly penumbra around the actual. The actual is the limit case of the potential, which is equally real; the one into which it collapses out of the many, as the particle is the collapse of a quantum field. (The particle is not more real than the field, rather it is a special case of the field, in which its field-like characteristics are at a minimum.) Similarly, the wholly determinate, were it to exist, which it does not, would be the limit case of the indeterminate.

Straight lines, in as much as they can be said to exist at all, do so as the limit case of curves, which constitute all the lines in nature (even space and the paths travelled in it are curved). Linearity is the limit case of nonlinearity, and can be approximated only by taking ever narrower views of an infinitely complex picture. The discontinuous, in as much as it can be said to exist at all, is the limit case of the continuous, which is the norm. Total independence is an imaginary construct, the limit case of *interdependence*, which is universal.

And the whole is shot through with purpose (a notion, by the way, that has nothing to do with some sort of engineering God), and endlessly creative, not pointless and passive. This cosmos is one from which we are never separate, but out of which we arise, in which we dwell, and to which, finally, we return.

My ultimate aim is to contribute a new perspective from which to look at the fundamental 'building blocks', as we think of them, of the cosmos: time, space, depth, motion, matter, consciousness, uniqueness, beauty, goodness, truth, purpose and the very idea of the existence or otherwise of a

God. These will form the subject of the last part of the book. Of course, these are vast topics, ones that have been grappled with by the ablest human minds for millennia; naturally I don't presume to try to settle the disputes that have arisen. Moreover, I am very far from being the first person to argue that the prevailing view is badly mistaken. But I do believe that the hemisphere hypothesis casts a very revealing new light on those disputes and strongly suggests that the view that has prevailed – a view heavily indebted to a belief in reductionism – very seriously distorts the evidence of the nature of reality that is before our eyes if only we would attend to it fully. It provides a genuinely new and compelling context in which to revisit these issues, one that may encourage us toward very different conclusions.

At the end of the book I shall return to considering the possible relevance of all this to the crises the world so palpably faces and to the condition of our own culture in the West. By then, though, I hope the relevance will have become all too obvious to the reader through following the argument of the book.

A BRIEF CLARIFICATION

Before I go any further, I am going to offer some indications towards an important aspect of the philosophical position I have come to espouse, and which I will advocate in this book. It is one that has arisen slowly through reflections on experience, and, in a way, I would rather have left an expression of it to emerge more slowly and organically out of what I will be going on to discuss. But I think that without some preliminary statement, however brief, the reader might jump to erroneous conclusions which may ultimately make it harder to see the fuller picture when we arrive there. I hope that questions I raise without addressing them immediately here will be found to be addressed in due course: my position will become much clearer as the book unfolds. These are my first words, by no means my last.

I wish, at this stage, to do little more than clearly distance myself from two positions. In the last century or so, there has been a tendency, at least in popular discourse, to pull reality in opposing directions. Some scientists, whether they put it this way or not when they are asked to reflect, still carry on as if there just exists a Reality Out There (ROT), the nature of which is independent of any consciousness of it: naïve realism. These are usually biologists; you won't find many physicists who would think that. In reality, we participate in the knowing: there is no 'view from nowhere'. Of crucial importance is that this fact does *not in any way* prevent science legitimately speaking of truths – far from it; a point I will return to in subsequent chapters. We desperately need what science can tell us, and postmodern attempts to undermine it should be vigorously resisted. Two important truths, then: science cannot tell us everything; but what science *can* tell us is pure gold. Any attempt to suppress science (I distinguish science sharply from technology), for whatever reason, is dangerous and wrong.

Meanwhile, on the other hand, there are philosophers of the humanities who think that there is no such thing as reality, since it's all Made Up Miraculously By Ourselves (MUMBO): naïve idealism. Such people, by the way, never behave as though there was no reality. Nor of course, by its own logic, can they claim any truth for their position.

These viewpoints are closer than they look. One party fears that if what we call reality were in any sense contaminated by our own involvement in

bringing it about it would no longer be worthy of being called real. The other fears that, since we manifestly do play a part in its coming about, it's already the case that it can't be called real. But just because we *participate* in reality doesn't mean we invent it out of nowhere, or solipsistically project it on some inner mental screen; much less does it mean that the very idea of reality is thereby invalidated.

I take it that there is something that is not just the contents of my mind – that, for example, you, my reader, exist. There is an infinitely vast, complex, multifaceted, whatever-it-is-that-exists-apart-from-ourselves. The only world that any of us can know, then, is what comes into being in the never-ending encounter *between* us and this whatever-it-is. What is more, I will claim that both parties evolve and are changed through the encounter: it is how we and it become more fully what we are. The process is both reciprocal and creative. Think of it as like a true and close relationship between two conscious beings: neither is of course 'made up' by the other, but both are to some extent, perhaps to a great extent, 'made' what they are through their relationship. If this seems at this point a step too far, the reader can, I hope, embrace a weaker position, that at least, as I say, our world is what comes into being in the encounter *between* us *and* this whatever-it-is.

The relationship comes before the *relata* – the 'things' that are supposed to be related. What we mean by the word 'and' is not just additive, but *creative*.

There is no one absolute truth about the world that results from this process, but there are certainly truths: some things we believe will be truer than others. A maximally open, patient, and attentive response to whatever-it-is is better at disclosing or discerning reality than a response that is peremptory, insensitive, or – above all – shrouded in dogma.

Importantly, what we experience is not just an *image* of a world 'outside', some sort of projection on the walls of a Cartesian theatre inside our heads, and watched by an intracerebral homunculus on an intracerebral sofa. As I will explain, such a viewpoint could be predicted to arise from the left hemisphere's attempt to deal with a reality it does not understand, and for which everything is a representation. True, we can deceive ourselves by mistaking our own projections for reality – and we often do; but that does not entail that we are always victims of self-deception. When we are properly attentive, what we experience is the 'real deal', though it be

only a tiny part of all that is. To appreciate that, you need the right hemisphere – and preferably, of course, both hemispheres – to be in play. It is true that we can see the world only partially, but we still each see the world directly. It is not a *re*-presentation, but a real *presence*: there is not a wall between us and the world. Our experience is *of whatever-it-is* and not another thing, even if we can't get away from the fact that it is we who experience it.

Yet, I say, we take part in its creation. How can that be?

An analogy may help get closer to what I mean. There is such a 'thing' as Mozart's G minor quintet. It is in a way quite specific. It certainly is not a fantasy, and it cannot be made up by me any way I want it. However, it doesn't exist in the closed score on my bookshelf (the potential alone is there). It doesn't exist in Mozart's mind, either, because he's dead, and the moment when he died made no difference whatever to the existence or the nature of the quintet. And there isn't a single *ideal* quintet that we are always imperfectly imitating in our encounters with it. It keeps coming into being, it keeps *becoming*, each time a mind, with all its history and preconceptions, encounters it, or when many minds do so together. Each time it will be real. And each time it will also be different, although it will be recognisably the 'same' piece of music. It is certainly not a matter of 'anything goes'. Not every rendition will be equally good, or equally true to the spirit of the quintet. And saying so should not be a problem: in life we don't find it difficult to discriminate between better or worse performances, and, crucially, we expect at least a degree of consensus on the matter among those who know enough to recognise a good performance when they hear one.

However, no-one would expect me to say precisely how I know that it is a 'true' performance of the work, let alone to prove to them that it is. At best I could point to certain aspects of the performance, and hope my fellow-listener picks up. And that's not just because of the particular nature of music. No-one expects me to say how I know that my understanding of *Hamlet* is more or less true, either. As a critic of *Hamlet* I state what I see: people either 'click' with what I say – get an insight from it – or don't. They either feel that I (and now they) know more about *Hamlet*, or they don't. This is not to give a single crumb of comfort to the 'my view is as good as yours' types. There are, very clearly, better and worse interpretations. I could get it indisputably wrong, for example, by claiming

it is really an account of peasant life in Azerbaijan in the tenth century, or, less dramatically, but nonetheless clearly, by claiming that it is primarily a critique of James I's foreign policy. There are in fact an almost limitless number of ways in which I am free to get it wrong.

I believe philosophy is like that. With the best will in the world, on both sides, I can't *make* you see what I experience as the truth. I can never convince you of a point of view unless you already, at some level, get it. As Friedrich Waismann put it,

We cannot constrain anyone who is unwilling to follow the new direction of a question; we can only extend the field of vision of the asker, loosen his prejudices, guide his gaze in a new direction: but all this can be achieved only with his consent.⁸

We can't make a plant from a seed; we can, however, choose to stunt it or permit it to flourish. I want to permit something that I believe is already there in the reader to flourish. Philosophy may at times aspire to be, but cannot ever be, coercive: it cannot compel to a point of view. It can only allow an insight to dawn. Sometimes this can happen quite suddenly: I hope that will be the experience of at least a few of my readers. Plato described the process as a spark that crosses the gap: 'suddenly a light, as it were, is kindled in one soul by a flame that leaps to it from another'.⁹ The truth is not arrived at ultimately by argument alone, though discussion plays a valuable role along the way in dispelling misconceptions (if it didn't, I would hardly have bothered writing a long book): in the end every individual must choose what carries conviction, commands allegiance. The experience of understanding involves a shift from what seems initially chaotic or formless, to a coherent stable form or picture, a *Gestalt* – or from an existing *Gestalt* to a new and better one, that seems richer than the one it replaces.

The idea of a *Gestalt* is central to this book: by it I mean the form of a whole that cannot be reduced to parts without the loss of something essential to its nature. Indeed, what I hope to offer in this book is just such a *Gestalt* – one that is based on an understanding of the import of the structure of our brains.

The flow of the universe is always creative, though it has order, and is not random or chaotic; the world is always a matter of responsiveness, though it is equally not a free-for-all. It is a process of creative collaboration, of co-creation.

In that spirit, I now want to modify my image of the quintet, which corresponds to some, but not all, aspects of reality. What if the music is not Mozart, but something more like some sublime jazz, or an Indian *raga* or Portuguese *fado*? Something we improvise – within bounds. Whatever it is will emerge from a balance of freedom and constraint. It won't exist until it is being performed: no-one can know exactly what it will be like. But it will not be random: it will emerge from the players' continuous interaction, and from the music's own 'history' as it unfolds; what comes next will be anticipated by what has gone before. It will also be moulded by the imagination, skill and training we bring, our past experience of playing (together and apart), the conventions of certain traditions, and shared expectations, quite apart from the fundamental laws of acoustics. Our co-creation of the music does not occur *ex nihilo*, and is not just a projection of ourselves. Yet we, and you, partake of its making, even if we are only listeners.

Our immersion in a culture of recorded music, in which we are passive and inert consumers, encourages us to think of music as a 'thing', separate from the hearer and the musicians who make it. Yet any performer who has had the experience of being taken up by the flow of either music or dance, of being 'in the groove', knows this is a dreadfully reductive account. To be in the groove, in the *flow*, is to feel oneself *played by*, as much as playing, the music. As Yeats says, 'How can we know the dancer from the dance?' ¹⁰

Again, just because I use music as an example, I am not making a point specifically about music. Music happens to be a very clear case of how what we take to be a thing emerges from a complex of relationships, both those between notes and those between individual consciousnesses. But all our experience, not just in music but in life, both mental and physical, is of such a complex flow, a constantly unfolding, responsive dance of reciprocal gestures. It exists in process and in relationship; our taking part in that reciprocity does not leave us inhabiting a solipsistic fantasy, but, precisely, confirms that it is *not* a solipsistic fantasy. We interact with one another and the world at large in a myriad ways without being able to have more than

limited control of the outcome. What comes to be does so through an interaction of a multiplicity of elements, some ours, some not.

Whatever-it-is-that-exists-apart-from-ourselves creates us, but we also take part in creating whatever-it-is. By this I do not only mean the common sense view that I have an impact on the world, as the world has an impact on me: that I leave my footprints. That would lead immediately to the reflection that I am very small in relation to the world, and so effectively my impact is so small that for all intents and purposes it can be ignored. There is, it might seem, an inexpressibly vast universe and an inexpressibly tiny individual consciousness (I'd say that this is the left hemisphere's attempt to represent spatially and quantify something that is experiential and developed in time, but I hope that will be more comprehensible when we come to the discussion of time and space in Part III). Such a reflection seems to posit an *objective* position – the view outside of history or geography, time or space – a view from nowhere, in which all can be measured and compared. It implies a Measurer of all the measurers, measuring the other scales and putting each part in its place according to its overall worth. But though that cannot be, the alternative is not just a merely *subjective* position, either: this very polarity – subjective/objective – is misleading. In the *fado*, in the *raga*, in jazz, it is what it is because of me, and I am what I am because of it. I will have much more to say about the crucial issue of the subjective/objective 'divide' throughout this book.

Similarly whatever-it-is is potential until the encounter: in each authentic encounter – one in which the individual truly apprehends and is apprehended by this Other – the Other becomes fulfilled. Each time this comes about in a unique fashion; but one that is not alien to the coming into being of that Other as a whole. And the actualisation, which at first seems to be a narrowing or collapse of potential, positively *adds* to the now enlarged field of the potential, which only discovers itself through (the repetition of) such actualisations.

Within my experience of the world, very much can be changed by my response to whatever-it-is – in a sense everything can be changed. Though that may seem to be 'just for me', how big or small is that? We cannot weigh consciousness against the universe. It is like trying to say precisely how much you love someone, if you really love them. It is not fixable in space or quantitative, but qualitative and experienced in the living flow of time. And if things turn out to be interconnected, not atomistic – and they

are – each consciousness has its impact on the universe that cannot be quantified.¹¹

Does this mean that there is no such thing as being wrong? Of course not. Though there can be no rules for jazz – indeed if it merely followed rules it would no longer *be* jazz – there are many things that just can't be done; much as in the middle of a flamenco dance, whose form is not predetermined, one cannot suddenly start balancing on one's heels, or stop and scratch one's nose, or do the can-can, without the dance ceasing to be. Flamenco is more formalised than jazz, but even in jazz there is literally no end to the list of what one doesn't do. However, there's no recipe, no procedure or algorithm to follow, for getting it right, either.¹² An algorithm is what the left hemisphere wants; the recognition that it's got to be free of any algorithm, yet not at all random, is characteristic of the understanding of the right hemisphere. We can specify what is not jazz, but not what is. Our knowledge of anything unique is similarly apophatic.

Just as 'and' is not merely additive, 'not' is not merely negative. Both are creative. Indeed resistance – 'not-ness' – is an absolute necessity for creation, another apparent paradox that will become clearer as this book unfolds.

That of which I have no inkling – whatever I just don't 'get' or 'see' – does not exist for me. That manifestation of whatever-it-is is simply not available in my world. But this doesn't mean that things come and go from everyone else's reality dependent on my understanding of it. If I can't see the moon, that doesn't mean it stops being there for others. If we are all tuned in to the same whatever-it-is – and I believe it makes no sense to assert we are not – something very like what I can't see is probably being seen by others, and ultimately that will affect me. It is perfectly possible to be deceived about, or to be in denial about, an aspect of whatever-it-is.

As I hope to demonstrate, there is much evidence that the left hemisphere is less veridical, more ready to embrace denial and more likely to be taken in by an illusion than the right. For that to be the case, there has to be some test of reality. Truth certainly has a meaning – I shall explore this explicitly in Chapter 10, which is devoted to the question. But truth, like reality, is an encounter. It is in the nature of an encounter that more than one element is involved. And what *I* find in whatever-it-is does not pre-exist my encounter with it. There must be a potential, true enough, but it is actualised only in my encounter with it. The encounter is genuinely

creative. The whole universe is constantly creative – but not out of nowhere.

We are dealing here with a phenomenon or process whose shape can be intuited, but to which our everyday language is not well adapted. When the world is viewed as a flow, albeit a differentiated one, rather than as a succession of points or a world of *things*, these problematic formulations can be approached from a fresh point of view, wherein many of the difficulties get to be resolved. But that is to jump ahead. For now, I will simply say that I hope that in what follows the reader may come to see grounds for a view that the world is a seamless, always self-creating, self-individuating, and simultaneously self-uniting, flow that is only truly knowable as it comes to be known. (I say ‘it’, for convenience at this point; it is a question worth considering whether this is the appropriate pronoun.) ‘It’ is like a stream, with its whirlpools and eddies, that come into being for a time, and resolve; while they are there they are present to all observers, even measurable up to a point; and yet, while distinct, they are inseparable from the stream, not just in the sense that without the stream they do not exist, but in the sense that they *are* the stream. And creativity is always discovery of the self as well as of the other.¹³ Once one sees this, the objectivising, time-denying, change-denying, diagrammatic mentality of modern Western thinking appears as I believe it is: a hindrance, not a help, on the path to truth.

The world we know cannot be wholly mind-independent, and it cannot be wholly mind-dependent. Once again, this leaves no room for a philosophy of ‘anything goes’. What is required is an attentive response to something real and other than ourselves, of which we have only inklings at first, but which comes more and more into being through our response to it – if we are truly responsive to it. We nurture it into being; or not. In this it has something of the structure of love.

Where this leads will, I hope, be clearer by the end of the book, when I will return to its implications. As I say, I have reservations about the usefulness of such a statement as I have given at this stage. It is rather like trying to convey the ‘meaning’ of a novel or a film by a couple of sentences outlining the plot in advance. The very people for whom this excursus was designed are the same ones at risk of getting too hung up on the detail of terminology, rather than seeing what is being pointed towards. That can only be recognised, not defined: in this it is like the Zen image of the

philosopher pointing at the moon, while those around him are focussed on his finger. If I may borrow the words of Fichte:

I have sought so far as possible to avoid a fixed terminology – the easiest way for literalists to deprive a system of life, and make dry bones of it ... It will be necessary first to obtain a view of the whole before any single proposition therein can be accurately defined, for it is their interconnection that throws light on the parts; a method which certainly assumes willingness to do the system justice, and not the intention of merely finding fault with it.¹⁴

Once again, the whole illuminates the parts as much as the parts can illuminate the whole. To the left hemisphere, you find the truth about something by building it up from bits. But, as the right hemisphere is aware, to *understand* it you need to experience it as a whole, since the whole reveals as much about the nature of the parts as the parts do about the nature of the whole.

This clarification was necessary, because I will be explaining that the world we experience – which is the only one we can know – is affected by the kind of attention we pay to it. This implies that there is no simple and single, wholly mind-independent, truth. What I did *not* want to appear to be saying, at any cost, was that there is no such thing as truth; or that reality is simply made up at our whim. Absolutely not.

ATTENTION AND THE BRAIN

Attention changes the world. How you attend to it changes what it is you find there. What you find then governs the kind of attention you will think it appropriate to pay in the future. And so it is that the world you recognise (which will not be *exactly* the same as my world) is ‘firmed up’ – and brought into being.

What, then, is attention? Is it really just another ‘cognitive function’ of that supposed ‘machine’, the brain? It’s clearly something pretty special if it takes part in the creation of the only world we can know. Is it a thing? Hardly. Is it something we do? Nearer, but not exactly. Perhaps a manner of doing? Or even a manner of *being*?

The best way I can put it is that it is the manner in which our consciousness is disposed towards whatever else exists. The choice we make of how we dispose our consciousness is the ultimate creative act: it renders the world what it is. It is, therefore, a moral act: it has consequences. ‘Love’, said the French philosopher Louis Lavelle, ‘is a pure attention to the existence of the other’.¹⁵

In *The Master and his Emissary: The Divided Brain and the Making of the Western World*, I aimed to dispel the unscientific fiction, popular at the time, that there was no significant difference between the hemispheres. This misconception was just as popular, and just as absurd, as any of the myths about supposed differences that were, and for all I know still are, being peddled in management seminars, and to which it was a knee-jerk reaction. In reality, as anyone who has worked with neurological and psychiatric patients knows, there is a world of difference between the two hemispheres: literally, since they give rise to two different *experiential worlds*. The question was not whether there was a difference – that was clear, beyond a shadow of a doubt – but *why* there was, and *of what kind* it might be.

My argument was, and is, that the nature of the difference between the hemispheres is far from anything hitherto imagined, and that it fulfils an evolutionary purpose of the utmost importance. It is not a separation of reason from emotion, or language from visuo-spatial skills, or any of the other things that used to be said, since, indeed, each hemisphere deals with absolutely everything – just in a reliably different way. The character and

sheer extent of that difference, as well as its significance for the future of our civilisation, formed the subject of that book. And that difference could be seen as rooted in a difference in attention, as I shall explain.

Many of the findings of neuroscience simply offer us a description of the brain correlates of human experience. For example, it is hardly a revelation that certain parts of the brain ‘light up’, as we say, on a scan, when we fall in love. Something has to, because every single experience you have has its correlates in the brain somewhere, and where exactly that may be does not tell us much about the experience of falling in love. As such, these and other similar findings offer a description of experience at a reduced level, but do not directly illuminate the nature of that experience. By contrast, my thesis, though it depends on neuroscience, has no reductionist agenda. I do not claim for an instant that our experience merely *is* some function in the brain. Quite the contrary, in fact, since my thesis implies that only one part of our brains – the part that understands less – would pursue such an agenda in the first place.

Some philosophers deny that scientific research can tell us anything at all about human experience, on the grounds that experience is an ‘inward’ matter (which is undeniably the case). By definition, or so it is said, our experience is the authority on what it itself is, and we cannot get a better handle on it by the approach from ‘outside’. Sympathetic as I am to this position, I cannot entirely agree. There are some aspects of our experience which, while perhaps not technically impossible to discover by introspection, are relatively opaque, since, for reasons of survival, nature has taken care to hide them from us. Too great an awareness of them would bring life to a standstill. But they may be nonetheless important for all that.

For example, take a look around you at the room in which you are sitting. Much of what you believe you are seeing is not actually seen at all, but is filled in at a level below conscious awareness on the expectation of familiarity. And we know this, not from introspection, but from neuropsychological research. There are many such aspects of what has been dubbed the ‘grand illusion’ that is our daily experience of the world, and ingenious experiments can sometimes bring them to light. Some of these experiments have become part of entertainment culture and are by now well known.¹⁶

Examining the brain, then, can sometimes add to our knowledge of what it means to be a human being, precisely because in some areas direct

knowledge from experience is providentially shielded from us. And there is one very important aspect of experience, right at its centre, that we are not aware of as experience unfolds, because awareness of it would bring life to a standstill. That is the fact that our experience is constantly synthesised from the divergent 'takes' on the world offered to us by each of our brain hemispheres.

SOME CORE IDEAS OF THE HEMISPHERE HYPOTHESIS

In one way, the hemisphere hypothesis is deceptively simple: the bi-hemispheric structure of the brain makes possible attending to the world simultaneously in two otherwise incompatible ways. It is the implications of this that are manifold. Immediately it gives rise to a number of further hypotheses: that this is a requirement of survival; that this difference underlies and makes sense of a host of observable cognitive and emotional differences that in its absence appear inexplicable and incoherent; that it underlies and makes sense of otherwise unexplained aspects of the relationship between the hemispheres, both structural and functional; that it explains the tension between phenomenologically different experiential worlds. And that that, in turn, helps to illuminate aspects of philosophy and psychopathology. In place of what hitherto looked like a myriad discrete pieces of information that one must accept with a shrug ‘just *are* that way’, there emerges a coherent picture that has meaning. When I refer to the hemisphere hypothesis from now on, I mean the whole of this set of hypotheses, and the overall picture they make possible.

Can all this be compressed into a few sentences? No, but I do understand the need to say *something*. So what follows is a crude summary, the best that can be hoped for in a short space, provided principally as a kind of aide-memoire to the reader of *The Master and his Emissary*, with no attempt here at nuance, or to argue a case, or adduce evidence.¹⁷ All that is taken care of in the book from which it derives.

In brief, then, a few questions; and then a few possible answers.

- The brain is asymmetrical in almost everything that can be measured, at many levels, in both its structure and function. Why?
- The power of the brain exists only through making connexions (between neurones) – and the reach of that power depends on the number of connexions it can make. Yet it is deeply divided down the middle. Why?
- The principal band of fibres that connects the two hemispheres at their base in humans, known as the corpus callosum, has got

proportionately smaller, not larger, over evolution – and is, in any case, to a large extent inhibitory in function. Why?

Fig. 1. Human brain, displaying the corpus callosum, from Andreas Vesalius, De humani corporis fabrica (1543): Book VII, Plate 3. The left hemisphere is retracted to display the corpus callosum ('L') in the midline, joining the two hemispheres at their base

The full answer to the last of these is, I believe, more complex, and even more intriguing, than the answer to the others, and it is a story I will turn to in Chapter 1. But there is one observation that lies behind the answer to all three questions, and makes perfect sense in Darwinian terms.

Every animal, in order to survive, has to solve a conundrum: how to eat without being eaten. It has to pay precisely focussed, narrow-beam attention that is already committed to whatever is of interest to it, so as to exploit the world for food and shelter. Put at its simplest, a bird must be able to distinguish a seed from the background of gravel on which it lies, and pick it up swiftly and accurately; similarly, with a twig to build a nest. Yet, if the bird is to survive, it must also, at one and the same time, pay another kind of attention to the world, which is the precise opposite of the first: broad, open, sustained, vigilant attention, on the lookout for predators or for conspecifics, for friend or foe, but also, crucially, open to the appearance of

the utterly unfamiliar – whatever may exist in the world of which it had no previous knowledge.

How on earth can you dispose your consciousness towards the world in two conflicting ways at once? The answer is the evolution of *two* neuronal masses, separate enough to function independently, but connected enough to work in concert with one another, each capable of sustaining consciousness on its own. In other words, a bipartite brain. Thus the need to sustain two incompatible ‘takes’ on the world simultaneously explains, I believe (and there is no significant competing theory), the extraordinary fact that the brain is so deeply divided, an otherwise inexplicable waste of potential in an organ that exists only to make connexions, and whose power lies, precisely, in the number of connexions it can make. And since the two halves have different roles, it makes sense that they are not mirror images of one another. Every single creature’s nervous system that we have studied is asymmetrical in nature, and where there is an identifiable brain it has this bipartite structure.

In birds and other animals studied, there is a highly significant separation of attention, with the left hemisphere being used largely for paying narrow-beam, sharply focussed attention to the world, for the purpose of manipulation, and the right hemisphere for paying open, sustained, vigilant attention to the world, in order to understand and relate to the bigger picture. The right is also the hemisphere with which creatures approach, appraise and ultimately bond with their mates.

At this stage I should point out to a reader new to the area that the right half of the brain controls and responds to the left half of the body, and vice versa. That means that motor and sensory function, as well as all manner of perception (except, oddly, for the sense of smell) from one half of space, both internal and external, is relayed to the opposite side of the body. Why this is the case throughout the vertebrate animal kingdom is not known for certain, though a number of possible explanations have been put forward.¹⁸ However, for the purposes of this book, nothing hangs on *why* it should be the case.

When it comes to the visual field, once again, in most animals, the left eye straightforwardly feeds information to the right hemisphere and vice versa, where the eyes are on the sides of the head. However, in humans the situation is slightly different, since we have eyes on the front of our heads. That means that the left visual field of *each* eye (both right and left) feeds to

the right hemisphere and, of course, the right visual field of *each* eye feeds to the left hemisphere (see Plate 1[d]).

The detail is not the important thing to remember. The point is that, very broadly, the right hemisphere *attends to* the left half of the world (in reality much more, but that can wait till Chapter 2), and the left hemisphere (pretty much solely) to the right half.

Attention is *not* just another ‘cognitive function’: it is, as I say, the disposition adopted by one’s consciousness towards the world. Absent, present, detached, engaged, alienated, empathic, broad or narrow, sustained or piecemeal, it therefore has the power to alter whatever it meets. Since our consciousness plays some part in what comes into being, the play of attention can both create and destroy, but it never leaves its object unchanged. So how you attend to something – or don’t attend to it – matters a very great deal.

By paying a certain kind of attention, you can humanise or dehumanise, cherish or strip of all value. By a kind of alienating, fragmenting and focal attention, you can reduce humanity – or art, sex, humour, or religion – to nothing. You can so alienate yourself from a poem that you stop seeing the poem at all, and instead come to see in its place just theories, messages and formal tropes; stop hearing the music and hear only tonalities and harmonic shifts; stop seeing the person and see only mechanisms – all because of the plane of attention. More than that, when such a state of affairs comes about, you are no longer aware that there is a problem at all. For you do not see what it is you cannot see.

Nothing ever comes to attention as an unformed percept: we always see something ‘as’ a something, whether we are aware of it or not.¹⁹ And that ‘as’ is always a partial truth with practical consequences for the encounter. For instance, there is no one way of ‘truly’ seeing the body. I have a different experience of what the human body is depending on whether the body is that of a patient, the victim in a crime I am investigating, my aunt, an artist’s model, or my lover. Each calls forth, and expects to receive, a different kind of attention, which governs what, in the end, it is that I experience.

Behind the house where I live there is a mountain whose description in Norse, *t-hallr skjær*, ‘the sloping rock’, is said to have given the place its name, Talisker. What this tells us is that, for the early Viking settlers in this remote part of the Scottish islands, the mountain was a valued landmark

clearly recognisable by its sloping outline from the sea. Still earlier, for the Picts whose ruined brochs show that they had lived in its shadow, it had meant both human shelter and the home of the gods; later, for eighteenth- and nineteenth-century travellers, it was a many-textured form of beauty to be engraved or painted; to the geologist, it is a notable example of columnar basalt formation; to a speculator it is a potential source of wealth; to a physicist it is 99.99% space, populated sparsely by particles of we know not what, that have only probabilistic existence there at all.

Which of these is the ‘real’ mountain? Each way of attending produces a mountain seen ‘as’ – something different. None of these ways can be said to be the ‘real’ way, for each is partial; and yet they are not illusory either. Neither is it ‘really just a lump of rock’, because that is, far from being an escape from subjectivity, to jump into it headlong. It is just another very partial way of seeing the mountain, the reductionist view: full of attitude, unexpressed goals and values – above all, that it is the only true view – and, while certainly seeing something, for most purposes leaving everything important out.

That attitude becomes particularly troublesome when one reaches the living, because here, too, there is a naïve assumption that the most reduced description is somehow the most real. We are really ‘just’ aggregates of cells, genes or particles, at whatever level of breakdown one likes to pause the analysis (it really doesn’t matter which, because there is always another level to go to on the way down to the *completely* unknown, at which point one has nothing and can say nothing: choose your own). The deception in this vanishing trick seems particularly hard to spot for those who pride themselves on their lack of self-deception.

The type of attention, then, is critical to what it is that one sees when one encounters the world. And encountering the brain is no exception. If one attends to it in one way, one sees a piece of machinery. If one attends in another, one sees part of a person. Crucial difference, for reasons I have already touched on. Ask the ‘machine’ question, and you find that each hemisphere is involved with ‘processing’ language, reason, music, emotion, imagery, morality, the self and much else besides. This could lead, and has led, people to say that there is no difference between the hemispheres. But each is involved with all these areas in a consistent, and consistently very different, way, as I demonstrated in *The Master and his Emissary*. It is not the what, but the how, that matters – as it does with the living person.

The right hemisphere is not just vigilant in a somewhat passive way. It is constantly engaged in both sustaining coherence in the world and actively scanning the world. What may in some cases later become a target for the left hemisphere's narrow focus will most probably have been first detected by the right hemisphere's broad search. Though, as the seconds pass, there is a tendency to shift towards more focal investigation of details initially revealed by the right hemisphere's overview – thus greater left hemisphere involvement – the search never becomes lateralised to the left.²⁰ And where a target is not obvious but needs to be actively searched out because, for example, it requires selecting something with more than one feature, this causes a large increase in activation of attentional areas predominantly in the right hemisphere.²¹ I will come to this in Chapter 2, but attention in general, and its nature, are more extensively underwritten by the right hemisphere than the left.

This distinction between narrow-beam, highly focussed attention in the left hemisphere and broad, sustained vigilance in the right has been repeatedly described not only in mammals, but in amphibians, reptiles and birds,²² as well as in fish, which are more likely, for example, to bite targets viewed on the right, the left hemisphere focussing on prey, than on the left.²³ The same predilections have been demonstrated in cuttlefish, who attack prey in the right visual field (LH) and scan for predators using the left visual field (RH).²⁴ Indeed, lateralised behaviours have also been demonstrated in many invertebrates,²⁵ including molluscs,²⁶ bees,²⁷ ants,²⁸ and spiders.²⁹ The slug *Limax* memorises food odours asymmetrically in its procerebral brain divisions.³⁰ Asymmetries of behaviour can be traced back more than 500 million years, and have been identified from fossils of trilobites.³¹ The nematode *Caenorhabditis elegans*, which evolved about 600 million years ago, and which has a nervous system of just 302 neurones, expresses chemoreceptors with left-right differences.³² As Onur Güntürkün puts it, 'if animals from nematodes to humans show asymmetries of brain and behaviour, we should expect that left-right differences provide some important fitness benefits'.³³

And it is not *just* a matter of sharing out the tasks, though that comes into it, because, if it were, the work would be both randomly, and equally, distributed. But it is not. It matters which way round the tasks are distributed.

Sometimes this phenomenon can be surprisingly marked, as demonstrated by an experiment in lizards. Lizards that use only their right hemisphere (left eye) in exploring a new environment react faster and more efficiently than those with a reverse pattern;³⁴ and the same, more successful, individuals, that use the right hemisphere for exploration and watching out for predators, also use the left hemisphere (right eye) for tracking prey.³⁵ In the experiment, lizards had a patch placed over one eye; they were then presented with a (simulated) predator, placed on the side of the non-patched eye. Lizards with the left eye uncovered naturally carried on using the left eye (right hemisphere) to monitor the predator, but – get this – lizards with the right eye uncovered, and the left eye patched, nonetheless tried to use the covered left eye.³⁶ Put this together with evidence that birds choose to examine predators with their left eye³⁷ to such an extent that if they happen to detect a predator first with their right eye, they will actually turn their head so as to examine the scene further with the left³⁸ – and a picture emerges. Conversely, there is a strong right eye (left hemisphere) bias for tool manufacture in crows, even where using the right eye *appears to make the task more difficult*.³⁹

Is this difference in attention, then, also true in humans?

Indeed it is – and that evidence I have covered elsewhere.⁴⁰ Not just the breadth (right hemisphere) and narrowness (left hemisphere) of attention are strongly preserved in humans, but even the predator versus prey distinction.⁴¹ I will have much more to say about how these differences in attention change the nature of the world that is perceived. But some preliminary remarks may help to orientate us to what is coming.

The narrow-beam, precisely focussed, piecemeal attention of the left hemisphere, aimed at a particular object of interest, is, as we have seen, the kind paid by an animal locking onto its prey. In humans the left hemisphere is designed for grasping, controls the right hand with which we grasp (as well as those *aspects* of language which enable us to say we have ‘grasped’ something – pinned it down) and helps us manipulate, rather than understand, the world. It sees little, but what it does see seems clear. It is confident, tends to be black and white in its judgments, and jumps to conclusions. Since it is serving the predator in us, it has to if it is to succeed. It sees a linear relationship between the doer and the ‘done to’, between arrow and target.

By contrast, the wide-open, vigilant, sustained attention of the right hemisphere, without preconception as to what it may find, is designed to look out for all the rest – whatever else might be going on in the world while we are busy grasping. Its purpose is to help us *understand*, rather than manipulate the world: to see the whole and how we relate to it. It is more exploratory, less certain: it is more interested in making discriminations, in shades of meaning. Since it is serving the survival instinct and the social animal in us, it has to be if it is to succeed. All relationships in this hemisphere's world reverberate, changing both parties, and there is no simple linear cause and effect. Its attention, one might say, is not so much linear as in the round.

According to our left hemisphere, reality should be independent of our observation. It is seen as a collection of things 'out there' – things that are effectively inert, unless moved mechanically, since they have no inner life of their own, and they are not involved with ours. Our life merely enables us to observe them in a detached way (the more detached the better, because then our observations are not contaminated by any input from us). Reality should certainly not be to any degree a product of the imagination, since imagination means – surely? – that we are deceived.

But what if, as our right hemisphere can more readily detect, it were not an essentially lifeless assemblage of things, but a constantly self-creating process? What if imagination was essential to the process of understanding – including, importantly, scientific understanding?

THE NATURE OF HEMISPHERE DIFFERENCES

There is nothing about the hemispheres that is symmetrical. That is not only, as I believe, a psychological truth with important metaphysical consequences – the theme of this book – but a brute physical fact. Asymmetries in the human foetal brain are visible to the naked eye as early as the 11th week of gestation.⁴² The hemispheres differ in size, weight, shape,⁴³ sulcal-gyral pattern (the convolutions on the cortical surface),⁴⁴ neuronal number,⁴⁵ cytoarchitecture (the structure at the cellular level),⁴⁶ neuronal cell size,⁴⁷ dendritic tree features,⁴⁸ grey to white matter ratio,⁴⁹ response to neuroendocrine hormones and degree of reliance on different neurotransmitters.⁵⁰ Added to which, as any clinician could tell you, it is not just the site, but the side, of a brain lesion that matters: it makes a huge difference to what happens to the subject's world. So the idea that there is no significant difference is simply a non-starter. It's just a question of what the differences are – and why they are there.

Students of animal behaviour not only find that the birds and other animals they study behave 'asymmetrically' (ie, to use their two hemispheres to pay predictably different kinds of attention), but that individual animals whose brain hemispheres are not sufficiently differentiated, and who do not exhibit the normal structural and functional asymmetries that are present in other members of their species, are at a competitive disadvantage and survive less well. This is summed up in an adage familiar to students of animal behaviour: 'asymmetry pays'.

In humans, too, an absence of the usual asymmetries of brain structure and function is detrimental. This was something that I had cause to ponder when I was engaged for a while in neuroimaging research at Johns Hopkins University Hospital in Baltimore, back in the 1990s. We were looking at structural asymmetry in the brains of subjects with schizophrenia, and found that in many cases the normal asymmetrical pattern was either absent or reversed. The reversed or absent asymmetries involved areas (known as heteromodal association cortex) that are important in language, social functioning and the business of making sense of the world at the highest level – areas of life that just happen to be those in which subjects with schizophrenia encounter major problems. What is especially fascinating is

that the abnormally symmetrical areas were often the result not of a failure to enlarge on one side but of a failure to shrink— or, at any rate, a failure to remain unenlarged — on the other. Was there something important not just about absolute size, but about *relative* size, and how this affected the equilibrium of a relationship? What was at stake?

As it happened, I already knew that attention was an important issue in schizophrenia. For example, subjects with schizophrenia fail to grasp the whole for being focussed on the parts. And I also knew that this was a characteristic difference between right (seeing the whole) and left (seeing the parts) in the brain.

Being aware of how one's attention shapes the world is not easy. And that's because there is a kind of vicious circle at work: the more one pays, for example, dehumanising, mechanising attention to the world, the more only those aspects of the world that can be construed in terms of mechanisms stand forth. The rest recedes. And, as they say, to a man with a hammer everything begins to look like a nail. The way we start out looking at the world soon hardens up; and after a while, any model comes to look like a surprisingly good fit, largely because everything that doesn't fit that model becomes helpfully invisible.

To say that attention grounds everything in the world of experience might still sound like just a manner of speaking, almost a rhetorical flourish. But in the chapters that follow we will see just how *literally* attention brings the experienced world into being. Everything we know is partly ours and partly not ours. Does the earth orbit the sun, or does the sun orbit the earth? Surely that's knowledge in which we play no part? Not actually: it depends on your point of view. When two masses are related in this way, seeing either one of them as still makes the other one appear to circle it. And one does not need to go to the quantum level in order to see how dependent reality is on our participation in it. Things that are very real, in the everyday sense that they can be recorded and measured, and experienced by anyone who is in the right place at the right moment, may nonetheless depend ultimately on consciousness to be what they are. I cannot summon up a rainbow at will, and yet its very real existence at a certain moment of time and space, dependent on factors clearly far beyond my control, such as rain and sunlight, is also dependent on my consciousness to view it, just as the sound of a tree crashing in a forest exists only in the presence of a hearing ear.

Let me sum up so far. There is nothing controversial in the view, undisputed by neuropsychologists and neurologists, that the hemispheres pay different types of attention to the world, in humans as in animals. It is similarly undisputed by neuropsychologists and philosophers that the type, and extent, of attention we pay changes the nature of the world that we experience. And since each hemisphere on its own is perfectly capable of yielding a coherent experiential world, the conclusion is therefore logically inescapable: that this situation should give rise to two different experiential worlds, with different qualities. It couldn't be otherwise. So there should be evidence that this is indeed the case. Is there?

Evidence from a wealth of sources, including brain insults (trauma, stroke, tumour, etc), neuropsychological experiments in normal and post-commissurotomy ('split-brain') subjects, and brain imaging in a range of modalities, suggests, precisely, that this is the case.⁵¹ This is a fact about human life, the implications of which are only now being uncovered. The evidence was available, however, from the turn of the nineteenth/twentieth century, and ignored or dismissed, a story I will come to later.

Before we move on, let me clear one misconception out of the way at this stage. I am aware that a hemisphere on its own cannot properly be said to do what only a person can do: 'believe', 'intend', 'decide', 'like' and so on. These and similar formulations should be understood as avoiding the repetition of such cumbersome locutions as 'a person relying on the faculties of the left (or right) hemisphere believes (intends, decides, likes)', etc. You are *not* your brain, you are a living human being, as philosopher of neuroscience Alva Noë emphasises: 'the idea that a person is a functioning assembly of brain cells and associated molecules is not something neuroscience has discovered. It is, rather, something it takes for granted.'⁵² And shouldn't.

Some of the headline differences, very much in shorthand form and for present purposes only, are listed below. For those who want to read more about each topic, I have included references in the notes to relevant pages in *The Master and his Emissary*, though these are not intended to be exhaustive.

1. The LH is principally concerned with manipulation of the world; the RH with understanding the world as a whole and how to relate to it.⁵³

2. The LH deals preferentially with detail, the local, what is central and in the foreground, and easily grasped; the RH with the whole picture, including the periphery or background, and all that is not immediately graspable. The importance of the global (RH)/local (LH) distinction cannot be overstated. It is also extremely robust.⁵⁴ ‘Perhaps the most compelling distinction between local and global visual processing is the differential lateralisation in the brain’;⁵⁵ ‘evidence to support this hypothesis comes from a wealth of data’.⁵⁶
3. The RH is on the lookout for, better at detecting and dealing with, whatever is new, the LH with what is familiar. VS Ramachandran calls the RH the ‘devil’s advocate’, since it acts as an ‘anomaly detector’, on the lookout for what might be erroneously assumed by the LH to be familiar.⁵⁷
4. The LH aims to narrow things down to a certainty, while the RH opens them up into possibility. The RH is able to sustain ambiguity and the holding together of information that appears to have contrary implications, without having to make an ‘either/or’ decision, and to collapse it, as the LH tends to do, in favour of one of them.
5. In line with this, the style of the RH is altogether more circumspect than that of the LH, which tends to be less self-critical.⁵⁸
6. The LH tends to see things as isolated, discrete, fragmentary, where the RH tends to see the whole. The LH tends to see things as put together mechanically from pieces, and sees the parts, rather than the complex union that the RH sees.⁵⁹
7. The LH’s world tends towards fixity and stasis, that of the RH towards change and flow.⁶⁰
8. The LH tends to see things as explicit and decontextualised, whereas the RH tends to see them as implicit and embedded in a context. As a result, the LH largely fails to understand metaphor, myth, irony, tone of voice, jokes, humour more generally, and poetry, and tends to take things literally.⁶¹
9. There is a tendency for the LH to prefer the inanimate, the RH the animate. Machines and tools are alone coded in the LH, too, while

the animate is coded by both hemispheres, though preferentially by the RH.⁶²

10. The RH understands narrative. The LH, if offered a story whose episodes are taken out of order, tends to regroup them so as to classify similar episodes together, rather than reconstruct them in the order that has human meaning.⁶³
11. Both hemispheres need to categorise, but do so according to different strategies. The LH tends to categorise using the presence or absence of a particular feature; the RH tends to do so by reference to unique exemplars, using what Wittgenstein called a 'family resemblance' approach – it sees the *Gestalt*.⁶⁴
12. More general categories are dealt with preferentially by the LH, more fine-grained ones, as one approaches more closely uniqueness, by the RH. Damage to the RH can lead to a loss of the sense of uniqueness or the capacity to recognise individuals altogether.⁶⁵
13. The RH contains the 'body image' (this is a slightly misleading neuropsychological term which refers not just to a visual image, but to a multimodal schema of the body as a whole). The LH tends to focus on parts – arms, legs and so on – out of which the body must then be constructed. The RH tends to process in a more embodied, less abstract fashion than the LH. The RH is also superior at reading body language and emotion expressed in the face or voice.⁶⁶
14. The LH is superior for fine analytic sequencing and has a larger linguistic vocabulary and more complex syntax than the RH. Pragmatics, the ability to understand the overall import of an utterance in context, is, however, a RH function. Understanding prosody, the musical aspect of language, its tone, inflection, etc, depends to a very large extent on the RH.⁶⁷
15. For most of us, music is very largely the province of the RH, the LH dealing only with simple rhythms.⁶⁸
16. The RH is essential for 'theory of mind': that is to say that it is better able to understand another's point of view.⁶⁹
17. The RH is essential for empathy.⁷⁰

18. In very general terms, both emotional receptivity and expressivity are greater in the RH.⁷¹
19. The RH is better at seeing things as they are pre-conceptually – fresh, unique, embodied, and as they ‘presence’ to us, or first come into being for us. The LH, then, sees things as they are ‘re-presented’, literally ‘present again’ after the fact, as already familiar abstractions or signs. One could say that the LH is the hemisphere of theory, the RH that of experience; the LH that of the map, the RH that of the terrain.⁷²
20. The LH is unreasonably optimistic, and it lacks insight into its limitations. The RH is more realistic, but tends towards the pessimistic.⁷³

These could be understood (LH-fashion) as 20 separate distinctions. Indeed that is how they have been seen, and still are seen, by most brain researchers. But they are (as the RH would see them) just an arbitrary number of attempts to give different sidelights on two distinct, entirely coherent versions of the world.

And it is the deep coherence of each world that is to me striking. People sometimes say to me, ‘the worlds of the two hemispheres that you describe stand on their own as having human meaning: do they need an evolutionary underpinning in the brain?’ Whether the picture *needs* such an underpinning or not, it *has* such an underpinning – and that underpinning has both theoretical intellectual import and lived human significance. Bipedalism (walking on two legs) helps to explain a number of findings that might not seem immediately connected, such as higher rates of death in childbirth compared with other species, differential retention of body hair on the top of the head, and the development of opposable thumbs that can make and wield tools. Knowing about the bi-hemispheric structure of the brain similarly helps to explain why certain facets of human thought and behaviour tend reliably to go together; it helps us to know ourselves, to recognise our strengths and limitations.

People have at various times intuited the relationship between one or two, or even several, of the 20 elements listed above that distinguish the hemispheres. Indeed, if I am right it would be odd if they had not. But they might not necessarily have seen why a detail-focussed vision, a tendency to see things as inanimate, problems with metaphorical understanding, and

unreasonable optimism, tend to go together; and, moreover, why we have difficulty seeing beyond a vision of the world that looks logical, but at a deep level isn't really logical at all. Whatever else, the hemisphere hypothesis helps us become aware of *who we are*, what it means to be a human being at all. It makes both immediate intuitive sense of disparate phenomena from the 'inside', and consolidates a view of ourselves that is verifiable from the 'outside' by massively detailed scientific data. This seems to me what the business of science at its best should involve.

So how might one characterise, as a whole, each hemisphere's vision of reality? One view, the left hemisphere view, is of a world composed of static, isolated, fragmentary elements that can be manipulated easily, are decontextualised, abstracted, detached, disembodied, mechanical, relatively uncomplicated by issues of beauty and morality (except in a consequentialist sense) and relatively untroubled by the complexity of empathy, emotion and human significance. They are put together, like brick on brick to build a wall, so as to reach conclusions that are taken to be unimpeachable. It is an inanimate universe – and a bureaucrat's dream. There is an excess of confidence and a lack of insight. This world is useful for purposes of manipulation, but is not a helpful guide to understanding the nature of what it encounters. Its use is local and for the short term.

In the other (the right hemisphere version), as in the world the map represents, and in the world revealed to us by physics, by poetry, and simply by the business of living, things are almost infinitely more complex. Nothing is clearly the *same* as anything else. All is flowing and changing, provisional, and complexly interconnected with everything else. Nothing is ever static, detached from our awareness of it, or disembodied; and everything needs to be understood in context, where, if it is not to be denatured, it must remain implicit. Here, wholes are different from the sum of the parts, and beauty and morality, along with empathy and emotional depth, help us to intuit meaning that lies beyond the banality of the familiar and everyday. It is an animate universe – and a bureaucrat's nightmare. This is a world from which we cannot detach ourselves, since we are part of it and affect it by our relationship with it. The overall timbre is sober and tentative. This world is truer to what is, but is harder to comprehend and to express in language, and less useful for practical issues that are local and short-term. On the other hand, for a broader or longer-term understanding the right hemisphere is essential.

Long before we had anything other than the most rudimentary knowledge of hemisphere difference, a number of philosophers – Pascal, Spinoza, Kant, Goethe, Schopenhauer, Nietzsche, Bergson and Scheler among them – were able to intuit that there are two fundamentally distinct ways in which we approach the world, what Bergson called ‘two different orders of reality’. I would tentatively suggest that many of the great questions of philosophy in fact turn on which one you choose, an idea I explore throughout the rest of this book. One way of looking at paradox is as an indicator that we are dealing with two apparently valid world-pictures which yet do not concur.

These two ways of seeing the world are each vital to our survival. We need to simplify and stand apart to manipulate things, to deal with the necessities of life, and to build the foundations of a civilisation. But to live in it, we also need to belong to the world and to understand the complexity of what it is we are dealing with. This division of attention works to our advantage when we use *both*. However, it is a handicap – in fact, it is a catastrophe – when we use only one.

SOME POTENTIAL CAUSES OF CONFUSION

So much for what I am saying. Equally important is what I am not saying.

a. Surely we all use our brains as a whole, not just one hemisphere?

Naturally, this is almost invariably the case. My point is a different one: that each hemisphere has inevitably a distinctive ‘take’ on the structure of the world, which is why we have two hemispheres at all. And each ‘take’ appears, when pondered in the abstract, strictly speaking incompatible with the other. They are each internally consistent, but mutually impossible. In the business of getting on with life, this is not a problem: we accept that the world is complex and multifaceted, and that truths are partial, and we wisely draw on what either hemisphere offers, as the situation demands, without even being aware of it. In neurological terms, the two versions of the world are evenly and rapidly drawn on, probably mediated by a meta-control centre in the midbrain (the head of the brainstem, and one of the most ancient parts of the brain), a process which is *necessarily* below the level of conscious awareness: if it weren’t, we would be incapable of acting.⁷⁴

However, we live in a society where talking about life is as much our defining quality as living it. And when it comes to articulating a philosophy, or a working model by which to understand our society and the wider world, that wisdom suddenly disappears in the mind of the public spokesman, politician or scientist in the need not to appear foolish. We become unnaturally self-scrutinising, and self-consistency suddenly becomes of prime importance. Regrettably we would rather speak falsely, if doing so means we do not seem to contradict ourselves: we realise that it is much simpler for our point of view to be dismissed as self-contradictory than untrue. Given this cast of mind, it is easy to see how one might easily argue one’s way into believing something which one knows perfectly well at a deeper level to be untrue. We are virtually forced to it by our desire to appear consistent to some – rather too simple – position.

Under these circumstances, two things follow. First, we are under almost irresistible pressure to adopt a view consistent with one

hemisphere's take or the other: it is too risky to draw, as we should, on both. And second, one of these takes, namely that of the left hemisphere, is very much simpler – indeed it is simplistic; and therefore far easier to articulate. It sees matters as black and white, 'either/or'. The right hemisphere sees the nuances, as well as that we often must embrace two superficially incompatible truths in a 'both/and' – one, moreover, that includes embracing both its own take *and* that of the left hemisphere: altogether a far harder, and more complex, view to articulate. (It is the purpose of education to enable us to do just this.) So it is clear which will get adopted by those who want to appear smart. The preference for consistency over truth is itself characteristic of the left hemisphere, as we will see; and it is inevitable that it results in an espousal of its own take.

b. 'Are you suggesting that the brain causes human experience?'

I do not suggest that the brain originates anything. I do not know that the brain 'causes' consciousness: it might or might not. For example, it might transduce, or otherwise mediate, consciousness. I have my own view on that, which I will come to in a later chapter. But it is a matter of likelihoods: I know of no way of proving the point one way or the other, since the observable facts would look the same whether it gave rise to, or simply mediated, consciousness: just as an alien could not tell merely by looking in the back of the TV set whether it gave rise to, or transmitted, the material it shows. In any case, nothing in the hemisphere hypothesis depends on the question being decided one way or the other.

Nor do I suggest that the brain determines events in the lived world – whether at the level of an individual or of a society in general. I *do* think one way of looking at human experience is to look at how it is shaped by the choices our brain permits us. But there are many other ways. For example, if you ask me why I robbed an old lady, I could reply: 'I needed the money', 'I had just watched a violent video', 'I inherited my dad's psychopathic tendencies', 'I was high on crystal meth', 'I heard a voice tell me to do it', 'I was brought up in a subculture where it was considered normal to steal', 'the government cut my welfare payments', 'my serotonin levels were depleted', and so on. What counts as a possible cause depends on the context of the question. I do not invoke the brain in order to trump other types or orders of explanation, be they psychological, sociological,

environmental, genetic, economic, technological or political, especially since they are inextricably intertwined one with another. Indeed, I do not attempt to ‘explain’ experience at all in the causative sense. Nor do I invoke the brain in order to tell us what experience ‘really is’, which it never could, but to illuminate the constraints on our understanding, which it can.

What I mean by that is best explained by analogy. While accepting that, by definition, no analogy can be exact when it comes to the brain and mind, because there is nothing at all like them to compare with, let me at least make the attempt.

Imagine you are studying the migratory patterns of a certain species of bird. Although we see them soaring and wheeling like free spirits – ‘free as a bird’, we say – they are subtly tethered to the earth. They have freedom to go where they want, it is true, but within certain constraints that are dictated by the realities of their embodied being. To understand a bird’s migratory patterns would require knowing something about the landscapes over which it flies – the opportunities for food and shelter they afford, the weather patterns they give rise to, and so on. These facts would not ‘cause’ the migration, still less are they themselves the migration, nor could they ‘explain it away’: they would simply indicate the constraints on the migration, that helped account for the pattern it *tended* to take. Sometimes, for contingent, or no discernible, reasons, a bird or birds might vary the pattern considerably and end up in Iceland instead of Scotland. But generally there would be a familiar shape to it, understandable in terms of the whole context: the nature of the land, sea, weather, fauna and flora through and over which the migration route passes.

Imperfect, inevitably, as the analogy is, I think it can hint at something about the relationship between our experience and the brain. Understanding the structure of the brain and how it functions can help us see the *constraints* on consciousness, much as, to use another metaphor, the banks of a river constrain its flow and are integral to its being a river at all, without themselves being sufficient to cause the river, or being themselves the river, or explaining it away. All experience in this life as we know it (and this applies whether we conceive the brain as the originator, or as a transducer, of consciousness) comes to us through the brain, and is therefore inevitably constrained, and shaped, by it. This is most obvious to us through there being many elements of our environment – certain pitches of sound, certain wavelengths of light, for example – that, though detectable by the

brains of other animals, are not detectable by ours. It also becomes obvious when, through some stroke, injury or other brain insult, aspects of normal experience disappear from the subject's world.

c. 'Are you suggesting that cultural changes reflect changes in brain structure?'

No. Of course the brain is evolving all the time, so strictly speaking there will be fine structural changes over a few thousand years, but it is not these I mean. The time period invoked is far too short for anything like that. It is not the changes in the brain itself that matter, but the way in which we use it. An analogy might be with a radio set: to begin with you try different channels, but after a while you begin to tune into only one. The other channels are still there – it's just that you are no longer listening to them.

d. 'Surely the hemispheres are always operative together?'

I frequently emphasise that both hemispheres are involved in absolutely everything we do. It cannot, however, be an argument against hemisphere differences. Both the scrub nurse and the surgeon are important members of the surgical team, and work together, at the same time, on the same task: an operation becomes hazardous in the absence of one, and impossible in the absence of the other. They work well together not because they have the same role, but precisely because they have different ones.

e. 'How can you talk of a hemisphere as a whole? It's all about local regions'

I do not deny the obvious fact that regions are important (one can subdivide them into ever smaller 'regions of interest' until one is looking at tiny clusters of neurones, and ultimately at the activity of a single neurone). Both in this book and in *The Master and his Emissary* there is detail about localisation, often in the notes, for those who wish to know more. But at the same time, there are emergent phenomena from the whole interconnected system at the hemisphere level, and neuroscience increasingly recognises that we should think in terms of complex widespread networks.⁷⁵ There are

two such networks, *par excellence*, maximally connected within themselves, that are each capable of supporting consciousness on their own: the two brain hemispheres. At the phenomenological level, they are the most important and complex collocations of neuronal matter underlying consciousness. The hemispheres are massively more intraconnected within themselves than they are connected to one another.⁷⁶

So, as in life, science needs both narrow focus and broad vision. Great work is done at the local level. This book is about what goes on at a higher level than that of intrahemispheric regions alone – though a very significant intrahemispheric distinction that will emerge regards the inhibitory effect of the frontal region of each hemisphere on its own posterior cortex. Nonetheless, this should not be thought of in purely antagonistic terms, but in dialectical terms, whereby something new is brought about through their joint action.

f. ‘The differences are not absolute’

This is, of course, true, and I often find it necessary to point out that hemisphere differences are never absolute. In biology scarcely anything is absolute. For example, left- or right- handedness, an issue I do not deal with in this book, and which is only indirectly related to hemisphere differences, is a commonly observed, highly significant phenomenon. But it is rarely absolute.⁷⁷ In a complex system like the brain it is never that there are black and white, all or none, differences – indeed, requiring them is itself a typical left hemisphere demand.

Many significant facts are found out only by tendencies in large data sets. Except in an imaginary world, almost all truths are of this kind. It is also to some extent a matter of judgment what is considered a significant difference.

Without generalisations we come to a standstill, but it is in the nature of generalisations to be imprecise and allow of exceptions. The average annual temperature in Indonesia is indisputably higher than that in Iceland, a fact that has many consequences for the vegetation, animal life, landscape, culture and economy of these two regions, as well as much else that differentiates their ‘feel’ and the ways of life in each country. If someone who knew them both well called them two different ‘worlds’, we’d know

what was meant. But it is also true that the highest average annual temperature ever recorded in Iceland is *higher* than the lowest average annual temperature ever recorded in Indonesia. There is overlap.

This comment on dualities is beautifully illustrated by the *taijitu*. There is a little bit of yin in the yang and a little bit of yang in the yin, and the duality of yin and yang, while remaining distinct, together compose a single perfect circle.

Furthermore, in the case of the brain, what may start out as small differences are inevitably magnified, since there is a ‘winner takes all’ principle at play. If one hemisphere is marginally better adapted than the other at a certain way of dealing with the world, it quickly becomes the preferred hemisphere to be involved in such tasks under virtually all circumstances, not just marginally more often than its counterpart. And with use it becomes better adapted still. Thus the hemispheres compound through experience the differences that genetics and embryology have laid upon them.

g. ‘But aren’t you dichotomising?’

I have not invented that hateful thing, a dichotomy. Some people are just against what they call ‘dichotomising’, feeling it is ‘simplistic’. But such a view is itself simplistic. There are, after all, different types of dichotomies. Some are inevitable, such as between plants and animals – even though there exist microscopic life forms that defy such categorisation. Some are entirely spurious. Elsewhere I have quoted

whoever it was who said that ‘there are two types of people in this world: those who divide the world into two types of people, and those who don’t’. Dichotomising has its problems.

An example of a very poor dichotomy would be ‘good drivers’ and ‘bad drivers’. There is no fundamental difference between the two. We have invented a dichotomy out of a continuum. It doesn’t make the distinction entirely meaningless, but it is not a good example of a valid dichotomy.

Then there are other continua where a dichotomy is more legitimate, though open to rather too many qualifications. For example, we can speak of left-wing and right-wing philosophies of society. This distinction does point to two underlying phenomena that are different in character, not just more or less of something. There is a continuum here, too, but it is between two, in themselves coherent, entities that, at least in their characteristic forms, are readily enough distinguished. There is more content, and more purpose, to the distinction here – misleading as I agree it can be at times.

Then there is a dichotomy based on the existence of two separate phenomena: say, Hinduism and Christianity. I am not saying that there might not be people who claim allegiance to both at once; nor that there may not be commonalities between the world views involved; nor, obviously, am I suggesting any form of antagonism between their proponents. I am just drawing attention, for the purposes of argument, to the fact that these are two coherent entities, which undoubtedly have points of overlap, but are generally distinct phenomena – culturally, historically and philosophically. This is an example of a dichotomy which it would be irrational to disregard, or pretend didn’t exist. It obviously does.

In other words, there are some dichotomies that have no basis, some that have a partial basis in fact, and some that it would be mistaken to pretend don’t exist. The division of the cerebral hemispheres falls into this last category, a ‘dichotomy’ made not by me, but by nature, which it would be profoundly irrational to ignore just because we don’t like dichotomies. Evolution has taken care to preserve, and even to intensify, the division of the brain, this organ whose whole purpose is to connect. The hemispheres differ in their structure and function at every level. So let’s not say we are dichotomising when we take a look at why that should be. What every intelligent person should want to know is: why is this the case? I am not saying I have all the answers, just some suggestions, appropriately backed by scientific evidence, and open to modification in the course of time.

All intellectual distinctions can be abused or misappropriated. Hemisphere difference is no exception. But the last thing we should do is ignore such distinctions, because ‘dichotomies’ don’t happen to fit the view of the world we already happen to have.

h. ‘The hemispheres are more alike than they are unlike’

This phrase has occasionally been used as if to counter the argument for hemisphere difference. But some level of likeness is not a proof that there are no substantive differences: indeed, there is little point in comparing any two things unless they have some broad similarities. It is as though I were to say, ‘there are fascinating and important differences between a cat and a mouse’, and you were to object that ‘they have more in common than they have different’. Whatever exactly this expression means (and it is not entirely clear), it is irrelevant, because sometimes it’s the differences that matter – as between Donald Trump and Albert Einstein, or an old banger and a new Ferrari. And so it is with the hemispheres: they have much in common, but, when contrasting them, it’s the differences that count.

i. ‘Actually, the hemispheres work in the same way’

Importantly we can describe, explain and understand complex systems at different levels. Those who stick resolutely to one level will fail to comprehend points made at another level. This fallacy is easy to spot for those with clinical experience of the brain as part of a person, because they see it every day; but it appears harder to spot for those who are more comfortable with machinery than human beings. As a result, some neuroscientists have difficulty shifting focus from the machine level, a level irrelevant to the differences that are being posited. (Actually the hemispheres do not work in entirely the same way even at a *technical* level – but that is beside the immediate point.)

Such objectors might, to use the same example, contradict the suggestion that the cat and the mouse see the world differently, along the lines that in order to see the world they both (as indeed do humans) use almost identical visual systems (involving the retina, optic tracts and radiations, tectum, visual cortex, etc), which comprise distinct dorsal and

ventral streams – and so on. Similar arguments can be made about every aspect of the organism as long as you examine them purely at the level of *mechanism*. This objection has its point, but the point is irrelevant, since cat and mouse ‘see’ the world (and perceive the world in other modalities) differently, and make sense of it in different ways, which are reflected in different types of behavioural responses that can be experimentally measured.

Moreover, these differences are not just single independent facts that have to be strung together, or extended from one area – say, vision – to another – say, hearing – because they are all part of one large underlying difference, which makes sense of the *whole*: what it means and what it takes to lead two very different types of life, that of the predatory cat and that of the watchful mouse. The basic mechanisms, at the technical level, that help them see are irrelevant, not just because they are largely held in common by cat and by mouse, but because they lie in the wrong plane of focus. It would be like trying to examine the difference between Fox News and Al Jazeera by focussing on the mechanics of studio lighting, cabling, cameras, TV signal transmission, cathode ray tubes, plasma/LED screens, etc – and solemnly concluding there was none.

This is particularly likely to happen the more we rely on imaging data, in which we are essentially looking at the detail of the ‘wiring’. By contrast, lesion studies, split-brain studies and tachistoscopic or dichotic-listening tasks (laboratory techniques that make it possible to separate input to each hemisphere), in which we are working at a more phenomenological level, are likely to be more revealing.

It may be responded that ‘the hemispheres are complex machines, not separate conscious beings’. But that is also misguided. A machine and a person are both just models that illuminate and obscure different aspects of the brain. The brain isn’t actually either simply a machine or simply a person. Each hemisphere can obviously sustain consciousness on its own – and appears to sustain not just different ‘cognitive strategies’, but different goals, values, opinions and emotional timbres, all of which are in reality inseparably interconnected with one another and with cognition. The ‘person’ model looks like a better fit than the ‘machine’ model, especially since a hemisphere is at least a manifestly important part of a person, and isn’t like any machine we have even got near inventing.

In 2003, four researchers who spent many years examining split-brain patients commented in a jointly authored paper in the classic textbook of neuropsychology, *Clinical Neuropsychology*, that, with experience,

examiners spontaneously refer to the two hemispheres as if they were distinct people, e.g., ‘the LH was upset at the RH responses today’. While such references may be regarded as shorthand for patterns of behaviour with specific lateralized stimuli and responses, they nonetheless express a strong phenomenological sense of two coexisting streams of consciousness. Both hemispheres can probably be simultaneously and independently conscious; both can simultaneously possess conflicting wills so that the split-brain can exhibit two distinct, and possibly incompatible, loci of moral responsibility.⁷⁸

Equally, research on split-brain patients taught Roger Sperry, who won a Nobel prize for this work,

that the two disconnected hemispheres function independently and in effect have each a separate mind of its own. Each of the separated hemispheres appears to have its own private sensations, perceptions, thoughts, feelings, and memories. Each hemisphere has its own inner visual world, each cut off from the conscious awareness of the other.⁷⁹

He also thought the evidence ‘favours the view that the minor [right] hemisphere is very conscious indeed, and further that both the separated left and the right hemispheres may be conscious simultaneously in different and even conflicting mental experiences that run along in parallel’.⁸⁰ In those days, notice, it was even necessary to argue that the right hemisphere was conscious at all. And Bogen, one of Sperry’s most distinguished colleagues, refers to two ‘crucial facts’: that ‘*it takes only one hemisphere to have a mind*’, and that ‘*hemispheres can sustain the activity of two separate spheres of consciousness following commissurotomy*’.⁸¹ Here is Sperry again:

Each hemisphere [in commissurotomy patients] can be shown to experience its own private sensations, percepts, thoughts, and memories that are inaccessible to awareness in the other hemisphere. Introspective verbal accounts from the vocal left hemisphere report a striking lack of awareness in this hemisphere for mental functions that have just been performed immediately before in the right hemisphere. In this respect each surgically disconnected hemisphere appears to have a mind of its own, but each cut off from, and oblivious to, conscious events in the partner hemisphere.⁸²

Thirty years after he first wrote about hemisphere differences in the *Scientific American*, Michael Gazzaniga, another giant in the field, who also worked on split-brain patients, was invited to revisit the topic in the light of three decades of research. His summary?

Despite myriad exceptions, the bulk of split-brain research has revealed an enormous degree of lateralisation – that is, specialisation in each of the hemispheres.⁸³

More recently, Onur Güntürkün, one of the leading researchers in the field of brain lateralisation today and a winner of Germany's most prestigious science award, the Gottfried-Wilhelm-Leibniz-Preis, for his work on lateralisation, has publicly supported the idea that the hemispheres underwrite differing aspects of personality, as well as, of course, attention and cognition: 'I believe that, at a deep level, McGilchrist is right. In the hemispheres, with their differing components and capabilities, lie different facets of the personality.'⁸⁴ And Claude Braun and Sabrina Suffren, a leading research team in lateralisation, see, as do I, a differing *disposition* that enables the hemispheres to work together and apart: 'the two hemispheres compete and co-operate with one another to maintain an online balance of two fundamentally opposed dispositions.'⁸⁵

The tendency in recent years has been to downplay the distinctions so clearly made here – possibly part of the general denial that has surrounded until recently the topic of hemisphere differences. When they have been referred to, the point made has almost invariably been, not that Sperry was

wrong to see what he saw – Sperry arguably spent more time observing commissurotomy patients than anyone who ever lived, and his conclusions were in accord with those of other observers, so that would be unlikely – but that it is a mistake to extrapolate from the observed differences in the hemispheres of a split-brain subject to the hemispheres of a normal subject, where such differences are not commonly manifest.

But this, too, is, I suggest, mistaken. That something is not manifest is not to say it doesn't exist. A marriage where one partner is domineering is exactly the situation where the couple may appear to be 'of one mind'. But to find out whether there truly is unanimity would require separating the partners sufficiently for their differences to be expressed. Before someone objects that the hemispheres are not a married couple, may I deflect such literal-minded thinking: the point is that real differences may be apparent only when circumstances permit. As I have pointed out, on introspection we are unable to detect that we have two kinds of experiential world, for the very good reason that the process of fusion goes on below the threshold of consciousness. The fact is manifest, however, as soon as one hemisphere, for whatever reason, stops functioning, as well as following callosotomy (the 'split-brain' procedure), but can even be demonstrated in normal subjects by experimentally suppressing one hemisphere at a time. In each case, these quite different experiential worlds are clearly, immediately, demonstrable. Where do those who deny hemisphere difference think they – in an instant – come from? Do they imagine they were suddenly created *ex nihilo*?⁸⁶ Furthermore, as I shall show in Chapter 1, the two hemispheres of the intact human brain have a large evolutionary investment in remaining distinct and to an extent autonomous.

For those who have read *The Master and his Emissary*, what will strike them about this list of misunderstandings is that it illustrates, in every case, a fallacy to which those who are over-reliant on left hemisphere thinking are vulnerable.

SHOULD ONE GO 'BEYOND THE FACTS'?

And there is another. Some people get uncomfortable if, as they tend to put it, one goes 'beyond the neurological facts'. This is, to be sure, an important point to raise: for where do the data cease and where does an understanding begin? What, we might ask, count as the 'facts' of the difference between the cat and the mouse? Is it just what you see from a neurological diagram, or is there more to it than that?

There is no hard and fast distinction here; it is matter of judgment to what degree we bring an understanding to bear on data. It is possible, then, to go too far, but also not to go by any means far enough. The human brain is where the physical world of measurable 'things' most intimately meets the rich complexity of human experience; when science is dealing with how consciousness brings the experienced world into being, it is not possible to avoid philosophy, including the history of ideas. Indeed the neglect of philosophy by science has been a disaster for science – and therefore for us all.

What counts, then, as going too far depends on a number of things, including the extent of the various hemisphere differences, whether there is any pattern or overall meaning to those differences, and the context in which you view them. If you don't know the extent of the differences (and very few people do), and if at the same time you can't see the overall picture (viewing the differences as just so much lab data, not something with significance for what it means to be a living person), then, yes, the argument has been taken too far. If you do and can, however – not far enough. Hence this book.

There's a world of difference between 'going beyond' the evidence, in the sense that your facts are wrong, and seeing the philosophical implications of those facts – how they hang together to create something greater, which inevitably 'goes beyond' them. That's what intelligent science is supposed to do – to progress beyond the mere accumulation of facts to an understanding of the question: 'who, then, are we?' Amassing facts on their own is not enough. Having said that, looking at an enormous amount of evidence is vitally necessary. The reader must judge for himself or herself whether the evidence is there.

I am not aware of a model that fits the data better. I don't say it is the last word; rather let it be the first of what I hope will be a new and fruitful discussion. The evidence is that that is already the case, and that's how science progresses. One model cedes to another. Or as the philosopher Alfred North Whitehead put it, 'in this way mankind stumbles on in its task of understanding the world.'⁸⁷ Understanding always means interpretation. Whitehead again:

The production of a scheme is a major effort of the speculative reason. It involves imagination far outrunning the direct observations ... Millions had seen apples fall from trees, but Newton had in his mind the mathematical scheme of dynamic relations: millions had seen lamps swinging in temples and churches, but Galileo had in his mind his vaguer anticipation of this same mathematical scheme: millions had seen animals preying on each other, vegetables choking each other, millions had endured famine and thirst, but Charles Darwin had in his mind the Malthusian scheme. The secret of progress is the speculative interest in abstract schemes of morphology.⁸⁸

'Abstract schemes of morphology': all advances in science are made by observing patterns, by using metaphors and formal analogies. And, if we wanted examples, we have them at the highest level: Darwin in biology, Freud in psychology and Bohr in physics spring to mind. Not observing patterns would be like trying to understand the famous picture of the Dalmatian dog by refusing to go 'beyond' the given dots and splashes.⁸⁹ Seeing the dog requires a functioning right hemisphere. The left hemisphere thinks locally, one dot at a time, and gets – nowhere.

I do not suggest that cultural shifts, epochs in the history of ideas, are caused by changes in our brains, but that they are shaped by the way our brains structure reality – or reflect reality's structure. We are constantly balancing, synthesising and alternating two entirely self-coherent, but on the face of it mutually incompatible, views of the world: we do it entirely unconsciously, and at the individual level most of us do it skilfully, in such a way as to respond appropriately to the richly diverse nature of experience. Understanding the hemispheric structure of the brain helps us see that,

when the world view of a culture changes, it does not do so as an assortment of bafflingly independent changing elements, but according to a broadly coherent pattern that makes sense overall. Public discourse in a culture can accentuate some ideas, concepts, beliefs and values at the expense of others. And when this happens, it is not as if these ideas, concepts, beliefs or values are atomistic; they bring with them a largely coherent world-picture, which gradually forms itself in the culture, and over time is expressed in a myriad of ways. I believe our own culture is unbalanced in the degree to which the left hemisphere's take predominates. And, unfortunately, the left hemisphere is decidedly imperceptive – and so is unaware there is a problem.

Science is far too great an enterprise to be fettered by the silo mentality of the left hemisphere. In the end, it seems to me that neurology, philosophy and physics must all be approaching the same core of reality, though from their very different starting points, and I would expect the picture ultimately to cohere.

THE ASYMMETRICAL RELATIONSHIP BETWEEN THE HEMISPHERES

Because of the asymmetry of attention, each hemisphere has a different take on everything – *including on its relationship with the other hemisphere*. This is best illustrated by the story from which *The Master and his Emissary* takes its title. There was a wise spiritual Master who looked after a small community so well that it flourished and grew. Eventually the Master realised that he could not take care of all his people's needs on his own; more importantly, he realised that there were certain matters that he not only could not, but *must* not, become involved in, if he were to preserve his overview. He therefore appointed his brightest assistant to go about and do work on his behalf. Though bright, this emissary was not bright enough to know what it was he didn't know. He became arrogant and resentful of the Master: 'What does he know?', he thought. 'I'm the one that does the real work round here, I'm the one that really knows.' And so he adopted the Master's cloak, and pretended to be the Master. The emissary not knowing what it was he didn't know, the community declined, and the story ends with the ruin of the community, including both the Master and the emissary.

Not ignorance, but ignorance of ignorance, is the death of knowledge. The right hemisphere, however, knows what it is that it must not get involved with. In the story that is why the Master (the right hemisphere) appoints the emissary in the first place.

You may imagine that, when I say things like 'the left hemisphere does not seem to know what it is it does not know', I am speaking purely figuratively. But I am not. There are plenty of examples – particularly vivid in the case of split-brain patients, but often seen in more common situations such as stroke – in which the left hemisphere not only clearly does not know what it is talking about, but behaves as though it knows perfectly well. Its manner is confident and unhesitating, even when it is talking about something of which it knows absolutely nothing (I will discuss some striking examples in Part I). By contrast, the right hemisphere tends to be hesitant, tentative and flexible, even when it is entirely right.

There are a number of reasons for this. The left hemisphere is aware of much less of what surrounds it – 'sees less', in all senses, than the right. It is

less tolerant of ambiguity and tends towards exclusive, ‘either/or’, thinking; the right hemisphere is more inclusive, inclined to ‘both/and’ thinking. This is imaged in the relationship of the two hemispheres: the right hemisphere communicates more, and more quickly, with the left hemisphere than the left hemisphere does with the right;⁹⁰ and the left hemisphere communicates more within itself, while there are ‘more bilateral interactions between hemispheres for the right hemisphere’.⁹¹ The phenomenological world of the left hemisphere is more self-directed, enclosed, self-validating – in thrall to its *theory*; the world of the right hemisphere more open to new information, the bigger picture, and what is actually the case, regardless of what the theory might suggest. All of which adds up to the right hemisphere seeing the relationship between the Master and emissary as co-operative, and requiring both parties, as the Master does in the parable; whereas the left hemisphere, like the emissary, sees itself as not needing (in truth it does not understand) what it is the Master knows. It’s a good servant, but a very poor master.

A map and the world it maps have a one-to-one relationship and each reflects the other’s reality. But the map is not of equal importance with the terrain it maps. Or another analogy: wearing glasses can sharpen your eyesight; but they only work if you have eyes. Relying on the right hemisphere alone could be thought of as losing your glasses, but at least retaining your eyesight; relying on the left hemisphere alone is a little like having your glasses on, but having your eyes tight shut. Oddly, you find there is nothing to see out there.

A narrow focus, serial analytic approach encourages us to think that the way to understand music is to see what is in each note, and then add them together to find out the sum. Or to understand flow by looking at a single molecule of water, or even at a small sequence of contiguous molecules of water, and work out from that what flow really is.

Two main consequences result from this fallacy of reduction to parts.

One is that the search goes in the wrong direction: not upwards, to understand how a phenomenon such as flow functions in the context of everything it takes part in, but downwards, towards units that not only do not exist as discrete entities, but, even if they did, would contain no more of the secret of flow than an agglomeration of single notes explains Beethoven’s *Missa Solemnis*.

The other consequence of the atomistic, serial, linear approach is a futile search for what causes what. As an example, a lot of effort has been, and continues to be, directed at disentangling what it is that the right hemisphere is contributing, when we say it is good at understanding metaphor. Is it its affinity for novelty? For complexity? For the implicit? For understanding utterances in context? Or for seeing the connexion between superficially unrelated elements? Which causes what?

This is a little like asking what explains the cat's success in catching mice. Its swiftness? Its agility? Its visual acuity? The sharpness of its claws? Its habit of going out hunting at night? Which is the primary quality? This is the typical left hemisphere approach: if we can only break it up into bits, we will finally understand it, by stringing the bits together in the right order.

My view is that this will lead to a somewhat unproductive argument. All these are together parts of the whole successful predatory animal that is the cat. No one element is the ultimate cause of the rest. They are part of the flowing process called evolution. (In fact many of the problems that people have with evolution come from seeing it atomistically, rather than as a flow.)

By contrast, we could approach this from the other direction, namely that many things are better understood by observing, not the 'parts', but the whole of which they are themselves part: seeing the *Gestalt*. I see metaphor as one aspect of the way we understand the world, something at which the right hemisphere is comprehensively better than the left, as I shall try to show in Part I. This way of looking also has the consequence that once you understand the coherent whole that is the right hemisphere's world, you can see that it would be odd indeed if the right hemisphere were *not* the better at understanding metaphor.

WHAT IS THE NATURE OF REALITY?

Philosophers in every known culture have debated the nature of reality from time immemorial. While we cannot, in the nature of things, ever pin it down, we cannot give up the search: understanding, like reality itself, is an unending process, not a thing that is finished so as to be grasped. It is the process that offers to enlighten us, not the act of appropriation. ‘It is not incumbent upon you to complete the work’, goes one rabbinical saying, ‘but neither are you at liberty to desist from it.’⁹² The truly foundational aspects of our experience – starting with consciousness itself – belong to the realm of things which permit no ultimate resolution. Indeed, some measure of our understanding of what we are dealing with is, precisely, the awareness that it forever exceeds our grasp. Not to be aware of the limits of our grasp of reality is folly, pure and simple. But, I emphasise, that does not mean that reality is whatever we happen to think it is, or would like it to be.

In an age that prides itself on being capable of resolving and clarifying every aspect of experience in such a way as to explain it, in the hope of controlling it, we are too apt, when faced with a question that cannot be answered, either to deny that the question has meaning, or to deny that the problematic entity exists, or both. It is not just Zen wisdom that is founded on pondering irresolvable questions, and paradoxical injunctions: you scarcely need to be a Zen master to see the deficiencies in the all too common modern Western strategy of ruling questions impermissible, or denying the existence of what we can’t comprehend. The most important questions are, precisely, the unanswerable ones.

In this book I will offer some thoughts about reality from a new perspective. To see this, we need to attempt what Shelley said was the distinctive achievement of poetry, when ‘it strips the veil of familiarity from the world’.⁹³ Imagine, then, for a moment, that it is not our world, but another, that we must explore. There are three questions to ponder, each taking us deeper into the unknown:

- What *means* do we have at our disposal in approaching this world?
- What *paths* should we follow in approaching this world?

- What can we say about the *form, the structure and nature* of this world?

In every case, I am interested to see what the hemisphere hypothesis can tell us.

In Part I, I address the *means* to truth, in the sense of the faculties with which we are endowed for this task. I take these to be: attention, perception, judgment, apprehension, emotional and social intelligence, cognitive intelligence and creativity (what I mean by each term will become clearer in the appropriate chapter). In each case I look at what either hemisphere contributes to the process. And here I hope an approximate analogy may help.

Suppose you are charged with gathering intelligence about a foreign country that has been infiltrated by two agents that continually report back to you. The agents have different skills, and different concerns aligned with those skills, so as to cover the range of information you require: you need to hear from both of them. Because of the exigencies of espionage, only one agent can have access to the transmitting device at any one time, and therefore has the task of reporting on behalf of both of them; each takes on this role at times but not according to any discernible pattern. Two things begin to be obvious to you: that the reports you receive often contradict one another; and that, as subsequent events unfold, some prove to have been highly reliable, others very clearly not. You suspect, rightly, that this is not random, but depends on who is doing the reporting. It thus becomes critical to identify, immediately on receipt, the reporter from which any message comes. Finally a breakthrough is made: computerised lexical analysis reveals there is a linguistic ‘fingerprint’ that enables you to tell whether a report comes from the reliable agent or not. This enables you to know which reports to act on; and from now on your progress is unstoppable.

In looking at each of the various means by which we gather information about the world listed above, as in the story there are two agents involved – the two hemispheres – and they cannot report separately. However, carefully designed experiments, and careful observation of ‘experiments of nature’, such as strokes, tumours and injuries, enable us to see what happens if one or other hemisphere is doing the ‘reporting’. This in turn enables us to do three things. First, we can come to a clear judgment of which is more reliable. Second, we can come to an understanding of why

reality so often appears paradoxical. And third, when faced with two differing accounts of the world, we can tell from the characteristic ‘imprint’ of either hemisphere on each account which is more likely to be reliable. Without, of course, wishing to discount either of them altogether, we can make a shrewd assessment of which we ought to prefer.

There is, naturally, no conceivable analogy for how the person relates to the brain, so do not overinterpret this analogy which is designed to make a limited point only. But if we (a) know which hemisphere is more trustworthy, and (b) can recognise the lexical signature, the ‘fingerprints’, of either hemisphere, we are already at an advantage. If I am right, this is a genuine advance in philosophy. That is the thrust of Part I.

Then comes Part II. Here I address the main *paths* that are open to us to take in our approach to truth. I take these to be science, reason, intuition and imagination. In each case I look at the strengths and limitations attendant on them; and bring to bear philosophical and psychological evidence and argument. I also look at what is contributed in each case by the right hemisphere and by the left.

Part III is the recompense for the painstaking examination of the portals (Part I) and the paths (Part II) whereby we can come to know the world. I look at the nature of the world, as disclosed by each of these paths and all of our faculties, and conclude that it looks nothing like the one that is commonly portrayed, but something far more complex, beautiful and alive – and that has immediate consequences for our understanding of what a human being is.

Against the view that whatever we have come to love, celebrate and honour is ‘nothing but’ something else, I suggest a different view: nothing can ever be ‘nothing but’ something else, because nothing whatever is *ever* the same as something else; that all that exists is more than we could ever be in a position fully to understand; that, far from being much less than we imagine, we are almost certainly far more than we *can* imagine. This seems like a more reasonable, as well as a more modest, proposal than that we know it all, at least in principle (‘some bits round the edges still need a bit of work, but we’ll get there soon, if scientific knowledge and technology keep expanding at their current rate’). In the words of William James: ‘Our science is a drop, our ignorance a sea.’⁹⁴ And that’s no less true now than it was then, since the more we learn, the more we see how much we have yet to learn.

Mallarmé said that poetry should evoke mystery.⁹⁵ So should science and philosophy, if it is true that there are no hard and fast boundaries between the different paths to knowledge, and that the following of all paths to truth leads ultimately to the same place. The wonder of science is not that its clarity reveals how clever we are, but that it reveals, like poetry, a deeper mystery. ‘The more we know’, writes astrophysicist Marcelo Gleiser, ‘the more exposed we are to our ignorance, and the more we know to ask.’⁹⁶

Our dominant value – sometimes I fear our only value – has, very clearly, become that of power. This aligns us with a brain system, that of the left hemisphere, the *raison d’être* of which is to control and manipulate the world. The whole point of its knowing is, simply, the better to control: as Francis Bacon famously put it, knowledge is power. But for us to be satisfied that we have power, the world must be seen to respond to our will, and work according to rules that we can know and operate, whenever and to whatever extent our will dictates. Any suggestion that some things are not amenable to this approach is taken as an affront to the onward march of the human intellect. Odd as it may seem, it is the very same people that view humans as little more than conniving apes that are most vain about their human capacity to know and do. The position seems to be that, however limited, commonplace and unamazing we are, the world is even more limited, commonplace and unamazing, since with all our shortcomings we can understand it. This could be contrasted with the view that marvellous as we are, the world is more marvellous than we have the capacity to understand. As the British nuclear physicist Emerson Pugh put it: ‘If the human brain were so simple that we could understand it, we would be so simple that we couldn’t’.⁹⁷

What I hope for my readers is that, if they are willing to accompany me on this adventure, they will never see the world the same way again; that they will have a *Gestalt* shift, as when this picture of a woman engaged in her *maquillage* is suddenly seen to be a grinning skull:

Fig. 2. All is vanity, drawing by Charles Allan Gilbert, 1892

Except that is a journey from life towards death. Our journey will be from death towards life.

THE MATTER WITH THINGS

*Our Brains, Our Delusions
and the Unmaking of the World*

Iain McGilchrist

The Ways to Truth

PART I

The Hemispheres & the Means to Truth

That the nervous system is double physically is ... a very striking fact, but one so well known that we are in danger of ceasing to think of its significance – of ceasing to wonder at it.

— JOHN HUGHLINGS JACKSON¹

This twofold nature of man is so clear that some have thought that we had two souls.

— BLAISE PASCAL²

1. Hughlings Jackson 1874. Hughlings Jackson is generally considered a towering giant in the history of modern neurology, and was one of the founders of the world-leading journal *Brain*.

2. Pascal 1976, §217 (Lafuma §532): « Cette duplicité de l'homme est si visible qu'il y en a qui ont pensé que nous avions deux âmes ».

SOME PRELIMINARIES: HOW WE GOT HERE

Le superflu, chose très nécessaire,
A réuni l'un et l'autre hémisphère.

—Voltaire¹

IF WE ARE INTERESTED IN TRUTH, WE OUGHT TO BE INTERESTED IN THE MIND through which it might be apprehended. To quote Roger Sperry:

Questions such as those concerning scientific truth, the nature of reality, and the place of man in the cosmos require for their study some knowledge of the constitution, quality, capacities and limitations of the human mind through which medium all such problems must be handled.²

And if we are interested in the capacities and limitations of the mind, we should be interested in the capacities and limitations of the brain. This book is my attempt to engage with just such questions through exploration of the extraordinary capacities, and as important limitations, of the human mind, and the brain that is its most direct embodiment.

This and subsequent chapters in Part I contain a certain amount of necessary neurological and neuropsychological detail. I hope that many people will find it as fascinating as I do, but I cannot expect that every reader will. For those who are prepared simply to take my word for it, I will provide a brief summary of the findings at the end of each chapter, that will

suffice to convey the general drift, but inevitably lack the vividness of specific details and descriptions of real patients, as well as much of the nuance. Those who want to know more about the evidence will, I hope, enjoy reading further. In Parts II and III, by contrast, the emphasis will be more philosophical than technical, and the conclusions to chapters there are not designed to act as summaries.

The most technical chapter is this one. If you survive this, you're good to go.

ANCIENT ORIGINS OF BRAIN STRUCTURE

I want to begin with some history: it is how we understand where we are now.

To make sense of hemisphere differences, we need to know how they evolved to be the way they are. Exactly why history took the path it did, as with all history, we can only hypothesise. In what follows I put forward a hypothesis of how and why the mammalian, and ultimately human, hemispheric system evolved to its present form. All I can say is that I know of no competing hypothesis that explains so many of the facts as we know them. And if you agree with my assessment, and follow through to Parts II and III, you will find many long-standing problems in philosophy are – not solved, of course, hardly – but reconceived in a way that might just help us make sense of the world, at a moment when we urgently need to do so.

To begin with, we need to go back long before the advent of the human brain, to the development of the very first nervous system of which we have knowledge. From there we can come forward to consider what happened with the advent of the mammalian, and finally the human, brain. What emerges is something like a dance. And, like many a good dance, it involves couples, their paths sometimes crossing, coming together and moving apart again, in a pattern that, viewed as a whole, makes perfect sense.

As the great English neurophysiologist Sir Charles Sherrington established more than a century ago, the proper working of the body depends on what he called ‘opponent processors’, systems that complement and counterbalance one another by their essentially opposing actions. A very simple example of this would be your arm, which requires not just the biceps, to flex it, but the triceps, to extend it; and the finely calibrated positions that are constantly required in real life can be achieved by employing both, to varying degrees, simultaneously. The nervous system is no exception. The autonomic nervous system, which regulates body functions below the level of consciousness, is divided into the sympathetic system, which prepares the body for action (‘fight or flight’), and the parasympathetic system, which prepares it for repose: again, the finely

modulated states that we require moment to moment are better carried out by opponent processors than one unidirectional system.

In the brain there are three main such pairs of opponent processors, ranged along each of the three spatial axes. There is the top-to-bottom axis: that is to say, the relationship between the cortex – the outermost layer, literally the ‘shell’, of the brain – and the regions which lie below it. (This is called the ‘dorsal-ventral’ axis, but the name is not important here.) There is the front-to-back axis, the relationship between the frontal cortex and the posterior cortex of each hemisphere. (This is called the ‘rostral-caudal’ axis, but again the name is not important.) Finally, there is the lateral axis, that of the two hemispheres. Each one of them involves a relationship of balance, that includes *both* mutual potentiation *and* mutual inhibition. I suggest that in each case the relationship began as one of reinforcement, and that their counterbalancing, or opponent, role emerged directly out of this over time. Intriguingly enough, this opponent role turns out to be far more creative than the merely reinforcing role could ever have been: one of the many themes of this book is the role of resistance in creation; and the working together of opposites.

It might surprise those who believe that the right/left story is an ‘urban legend’ to learn that lateral asymmetry is there right at the very origin of the nervous system. It was not an afterthought. It exists, as I mentioned earlier, in fish, amphibians, reptiles, birds, insects and nematode worms; but in fact the earliest known instance of a nervous system, that of *Nematostella vectensis*, a sea anemone over 700 million years old, already exhibits lateral asymmetry (see Plate 2 [b]).³ The head of the research team who made this discovery, Thomas Holstein of Heidelberg University, called it ‘the birth of centralisation of the neuronal network on the path to the complex brains of vertebrates’; and, he added, ‘the origin of a central nervous system is closely linked to the evolution of the body axes’.

Over evolution, as I described in the introduction to this book, asymmetry of the nervous system has been universally conserved as a means of addressing the problem of how to ‘get’ without being ‘got’. But to appreciate the full importance of laterality, we need to see how it interacts with the other two axes in three dimensions. Let us take a huge step forward, some 500 million years from *Nematostella*, to the first mammals.

With the mammalian brain, things take a whole new step, or series of steps, forward from the reptilian brain. The first mammals appeared in the

late Triassic and early Jurassic period, about 200 million years ago. They were small creatures at first, mouse- or shrew-like, probably nocturnal, living low to the ground, possibly subterranean dwellers. This way they kept out of notice of the much larger, but dumber, reptiles – the dinosaurs – with which they, for a while, co-existed, and which they eventually displaced. And there are, ultimately, three very important things about the mammalian brain, of consummate importance for understanding the nature of the human mind. One concerns the top-to-bottom axis – the development of the neocortex; the second concerns the side-to-side axis – the development of the corpus callosum; and the third concerns the front-to-back axis – the development of the frontal lobes. Each in some way has implications for all of the others. Let's look at them one by one.

First, the top-to-bottom axis.

THE DORSAL-VENTRAL AXIS

What is the neocortex? As its name suggests, it is a ‘new’ development compared with the simpler allocortex, on top of which it sits (see Plate 2[c]). It doubled the number of cortical layers from just three, in reptilian allocortex, to six. Since, broadly speaking, the power of the brain increases with the number of cell layers, the development of the neocortex with the first mammals is a radical shift in brain capacity.

What drove the development of the neocortex, which would one day become the home of all the higher conscious functions of mankind? The simple answer is that no-one really knows. But one likely hypothesis is that to survive in their various ecological niches these small animals had to be smarter than the lumbering creatures alongside whom they lived, and they needed sharper senses and proportionately bigger brains; their tetrapod ancestors had a relatively low-resolution sense of smell, poorer vision and hearing, coarser tactile sensitivity and unrefined motor co-ordination, with little of the cortex devoted to sensorimotor integration.

According to this hypothesis, the first driver of cortical expansion was the need for more sophisticated sensory information: specifically olfaction, and the sense of touch, these being especially significant in nocturnal creatures living close to the ground. The most striking feature of the first mammalian brains is the huge expansion of the olfactory bulbs and tracts.⁴ This was closely followed by tactile sensitivity. The need to conserve heat, given the proportionally bigger surface-to-volume ratio of small animals, made body hair a hugely important development in mammals (you lose heat through the body surface, and smaller bodies have, proportionately, bigger surfaces); but the primary drive may yet have been the extraordinary increase in sophisticated tactile-spatial information a coat of fur affords.⁵ In these early mammals, the neocortex is dominated by ‘a single primary somatosensory field’, mapping sensation from the greatly expanded olfactory bulbs, the skin, hair follicles, muscles and joints.⁶ More accurate sight and sound systems evolved only later,⁷ as did bimanual co-ordination, all of which particularly required close co-operation of the two hemispheres.⁸

In reptiles the equivalent sensory mapping is carried out in the mesencephalon, corresponding to what is known as the midbrain in humans (the midbrain is a small region situated at the top of the brainstem in an area below the hemispheres: see Fig. 3), beneath conscious access, and at a level where there is a well-developed cross-midline connexion, the tectal commissure.⁹ However, possibly because fibres connecting the hemispheres are relatively scarce in reptiles, the projections from there to the telencephalon, the higher, cortical area, lose their topographic organisation – ie, they are no longer, at that level, a map at all.¹⁰

Fig. 3. Sagittal section of the human brain showing the midbrain or mesencephalon

By contrast in mammals there is a map at the neocortical, the most highly evolved, level.¹¹ The development of this high-level map across the whole perceptual field in mammals is a crucially important step in the capacity for complex awareness of the world and the ability to make quick, subtle and accurate responses to it, the whole purpose of the elaboration of the vertical axis. What it required at this stage, above all, was the ability to *integrate* information, a process that could not be achieved across the relatively sparse connecting fibres of the upper levels of the reptilian brain. Clearly what mammals needed was a ‘superhighway’ connecting the two cortices. And this is where the corpus callosum comes in.

Thus the development of the *vertical* axis, for superior sensory mapping of the world, necessarily required strengthening the *lateral* axis. At first the corpus callosum would be there simply to facilitate. But remember there was, all along, a good evolutionary reason for separation: later it would become both a facilitator and an inhibitor, an all-in-one opponent processor. Similarly, at first the neocortex was simply doing more of what the allocortex did, and doing it better: it came, as these developments all did, in the service of enhancement of *already existing* cortical functions. Later, it would expand its repertoire vastly and come to be both a facilitatory partner and an inhibitory one – an opponent processor, exerting a downward inhibitory effect on the reptilian brain.

So, to the lateral axis.

THE LATERAL AXIS

The corpus callosum, then, just like the neocortex, is a mammalian invention.¹² To be precise, it is confined to placental mammals, since marsupials (effectively kangaroos, wallabies and opossums) and monotremes (egg-laying mammals, like the echidna and platypus) do not have a corpus callosum, any more than fish, amphibians, reptiles or birds: in its place they have anterior and posterior commissures, which are somewhat more substantial than in most mammals, in which they have now become fairly exiguous relics. But even these larger commissures are very slim indeed by comparison with the capacity of the corpus callosum.

I should note here that the callosum is often misunderstood not only as a unifying force, which it clearly often isn't, but also as the only means of communication between hemispheres, which it never is. The anterior commissure in humans, although very much smaller than the callosum (about a fiftieth to a hundredth the size), does transfer some information between hemispheres, and to an even smaller extent the slender posterior commissure does, too, though it is mainly concerned with pupillary reflexes. And even if these are cut, there is still subcortical communication by means of the brainstem and almost certainly the cerebellum. What's more, every single motor act initiated in one hemisphere gives thereby proprioceptive and visual feedback to the other hemisphere. And they share the influences of hormones through the blood supply, and of cerebral peptides through the cerebrospinal fluid, both of which, though slower-acting, are as important as neuronal communication for regulating mental states. So, even without the corpus callosum, the two hemispheres are not completely isolated.

However, the callosum remains by far the most immediate way in which the two hemispheres of the human brain interact, and it is the mediator not merely of connexion, but of hemisphere specialisation, as I will suggest.

It is thought that the callosum came into being in order to enable gaze pursuit of fast-moving objects across the midline, and to reinforce, more generally, perception in all modalities at, and around, the midline of the attentional field.¹³

But just as all the wealth of functions subserved by the human neocortex could not easily have been foreseen from its early expansion in the service of the sense of smell, the future uses of the corpus callosum can hardly be prefigured simply from the need to stitch together the midline of attention.

As the brain grew (and, as I say, mammals have proportionately much bigger brains than other animals), two things happened, which pulled in opposite directions. On the one hand, there was clearly a huge increase in the amount of information that needed to get across from one hemisphere to the other. But simultaneously, on the other, and for equally obvious reasons, the distances to be travelled were greater. This slowed down transmission. So what could be done about it?

One answer was for neurones projecting to the contralateral hemisphere, as far as possible, to shorten their route. This meant that fibres that, for instance, used to loop forward, cross to the other hemisphere, and then have to loop backward again, took a shorter path, nearer the middle of the brain: the initially slender hippocampal commissure began to be the route for more and more interhemispheric fibres, and eventually developed into the corpus callosum.¹⁴

The other answer was to increase transmission speed – to get ‘a faster cable connexion’. For this, the neuronal axons needed to become both thicker and sheathed in myelin. This is because thicker fibres and, even more, myelinated fibres, transmit faster (myelin is white, and is what differentiates white matter from grey).

But thicker fibres, which are then further increased in diameter by being encased in myelin sheaths, take up space – not just in the corpus callosum, but throughout the brain. A comparison of the fibre diameters in the corpus callosum of mouse and monkey suggests that the thickness of the fibres does not increase sufficiently to compensate fully for the longer distances in larger brains.¹⁵ Moreover, if brains were to remain proportionately interconnected as the number of neurones grew, the number of neuronal connexions of all kinds, inter- and intra- hemispheric, would have to grow *exponentially*. This is not only impossible, because of the external constraint of head size, but is self-defeating, because of increasing conduction delays. As the brain grows, then, and with it the complexity of its tasks grows, there has to be a trade-off. There comes a point where interconnexion must be limited.

One of the ways in which the need for interconnexion could be spared would be by *specialisation* of cortical areas. That way, only ‘results’ of (what would increasingly become) more local processing would have to be transmitted.¹⁶ In other words, functions could be delegated, and only what needed to be known outside of the area of delegation would be shared. Large administrative organisations are sometimes criticised, no doubt justly, because ‘the left hand doesn’t know what the right hand is doing’, but a degree of mutual ignorance is indispensable, provided the important outcomes are communicated.

And this is indeed the course that nature has taken.¹⁷ Cortical areas become more distinct as the mammalian brain has become more complex.¹⁸ The brain of the rat is small and its cortex is relatively unspecialised; the much bigger brain of the monkey has a cortex that is highly specialised.¹⁹ And, for example, the visual cortex of a cat is less specialised than that of a monkey and therefore more strongly influenced by other than visual – say, auditory – stimuli.²⁰ Generally the number of distinct cortical areas increases with brain size.²¹

Clearly, once initiated, this is a self-reinforcing process. More specialised units need to communicate less; with less communication, they become more specialised.

And this, in turn, has an effect on the corpus callosum. It does not simply require a decrease, or an increase, in its importance. It requires a change of function. What it means is that the callosum, too, needs to differentiate and *specialise*. Conduction times short enough to support common activity in both hemispheres are possible in only a few instances, not in all, and must therefore be sparingly allocated.²²

Bear with me while I make some distinctions. More connexion can mean more connexion – or *less* connexion, depending on whether the purpose of the first connexion is to say yes, or to say no.

The corpus callosum has both inhibitory and excitatory functions, depending on the areas involved and the nature of the task.²³ In humans only 2% of neurones in either hemisphere have fibres that cross the corpus callosum, so there is already considerable functional independence. Additionally while the majority of fibres that cross are in themselves facilitatory (employing the excitatory neurotransmitter glutamate), many of these connect with interneurones which employ the inhibitory

neurotransmitter gamma-aminobutyric acid (or GABA, for short), so that their overall effect is to inhibit.²⁴ So it is that we find that only a small population of large-diameter fibres continue to increase their diameter in species with larger brains.²⁵ These are the essential sensorimotor tracts that enable co-ordination across the midline of the attentional field – which was the earliest pressure, after all, for the evolution of the callosum.²⁶ It is here that speed is of ultimate importance. Indeed of all sensory input, integration across the corpus callosum of auditory and visual modalities is the most highly conserved, with high-resolution processing of central vision making possible accurate depth perception, and binaural cells generating a cortical sound localisation system: a sort of ‘sensurround’ experience.²⁷

For the rest, by contrast, most areas do not require the same urgent co-ordination, whether inhibitory or excitatory – especially where excitatory: the higher-order processing areas, involving more sophisticated cognitive functions are connected by smaller diameter, weakly myelinated, slower communicating, axons.²⁸ The overall effect is that when it comes to sensory and motor information, connectivity between homotopic regions (the ‘mirror image’ regions on either side) serves to co-ordinate the hemispheres in action; but where the most cognitively complex activity is going on, in the heteromodal association areas, communication is less important – unless it is actively to *suppress* one side or the other.²⁹ For, here’s the point: given specialisation and differentiation, one thing callosal tracts need to ensure is a sufficient degree of *non-interference*.³⁰ And that means there must be mutual inhibition. A balance between imparting information, at the sensorimotor level, and inhibiting premature involvement, especially at the cognitive level, needs to be struck.

Inhibition is creative. Here it leads to independence. Inhibitory interneurons are critical to normal functioning across a whole range of activities in the human cerebral cortex.³¹ The great Spanish neuropathologist Santiago Ramón y Cajal, sometimes referred to as the ‘father of modern neuroscience’, believed that the extraordinary power of the human mind was primarily dependent on the increase in the number and diversity of cortical *inhibitory* interneurons, many of which he was the first to identify: the power of opposites – ‘opponent processors’ – once again.³² The cortex of primates has many more, and a greater variety of types of, GABA neurons, reflecting greater sophistication of inhibitory

functioning, than the cortex of any other mammalian order.³³ In fact interneurons, most of which are inhibitory, constitute about 25–30% of the entire neuronal population in the cortex of primates.³⁴ And, within primates, the largest and the most numerous such interneurons, and the largest number of types of inhibitory neurons, are found in humans.³⁵

The evolution of larger brain size in primates, not just in humans, results in increasingly independent hemispheres.³⁶ This arrangement is more efficient for two main reasons: first, the avoidance of interference, especially in complex cognition; and second, a potential doubling of working capacity.

As regards the first, with age, for example, the corpus callosum of the human brain loses some of its capacity for interhemispheric inhibition, causing slower performance due to mutual interference.³⁷ Such interference may also underlie some aspects of psychopathology, as in schizophrenia, where transcallosal inhibition is less efficient.

As regards the second, when task requirements are demanding, performance is enhanced by distributing processing between the hemispheres,³⁸ both in split-brain patients³⁹ and in healthy volunteers.⁴⁰ Even when the tasks are simple, but conflicting, as in adding and subtracting at the same time, engaging both hemispheres independently is more efficient.⁴¹ Callosotomy patients are able to scan visual arrays for targets separately, thus being twice as efficient as normal subjects.⁴² They are also better able to carry out ‘mutually conflicting volitional decisions’.⁴³ Children of 10 are less able to use hemispheres separately than children of 12 and upwards: as a result older children can capitalise on using both hemispheres independently to solve problems.⁴⁴ Greater interhemispheric connectivity in girls was found to be associated with slower performance and with lower verbal IQ.⁴⁵ Greater hemisphere independence is associated with superior performance: ‘importantly’, as one research group report, ‘the magnitude of lateralisation [of functions] ... predicted the level of cognitive ability’.⁴⁶

By inhibiting the overall activity in one hemisphere, the corpus callosum may allow the other to take over for tasks more suited to its mode,⁴⁷ and thus maintain independence of the two hemispheres.⁴⁸ As activation builds in one hemisphere, the homologous region in the other hemisphere is inhibited:⁴⁹ stimulation of neurons in one hemisphere results

in an initial excitatory response in the homologous region in the other hemisphere, followed by a more prolonged inhibition.⁵⁰ These effects can be demonstrated on imaging.⁵¹

While theories have supported both what are described as ‘co-operation’ and ‘competition’ models of the relationship between hemispheres, these are not incompatible. It is clear that both are involved; and working separately, just as working together, can be in the service of greater efficiency.⁵²

In some respects, however, the hemispheres do seem to be in straightforward competition.⁵³ It has been observed since the late nineteenth century that the effects of a lesion in the central nervous system on one side may be paradoxically alleviated by a lesion in the corresponding position on the other.⁵⁴ For example, following a stroke affecting the speech area of the left frontal lobe, known as Broca’s area, improvement can result from temporarily disrupting the corresponding area of the right hemisphere.⁵⁵ Such studies ‘are difficult to understand in terms of traditional ideas that homologous cortical regions co-operate with each other across the midline.’⁵⁶ This is in keeping with my observation that in brains that have lost normal asymmetry the pathology is usually not that an expansion in a critical area of one hemisphere failed to take place, but that a failure to *inhibit* expansion in its contralateral homologue (the ‘mirror image’ location) occurred in the other.

But there is an asymmetry – of course! – in the relationship between the two hemispheres. In general, the right hemisphere communicates both more, and more quickly, with the left hemisphere than the left hemisphere does with the right.⁵⁷ This is exactly what one would expect if the right hemisphere is superior in perception, and more aware of what is going on: it’s more urgent that the left hemisphere learn from the right, than that the right hemisphere learn from the left.

However, it is not that the right hemisphere relatively neglects internal communication compared with the left. The right hemisphere is *both* more mutual *and* better integrated within itself. It has repeatedly been shown that, in the resting state of the normal brain, there is in general greater connectivity and coherence in the right hemisphere – both greater integration of information within the hemisphere, and a greater degree of interhemispheric transfer.⁵⁸ This is significant. In the words of Andrei

Medvedev of Washington's Center for Functional and Molecular Imaging, this provides 'the anatomical and functional basis for the existing view that the left hemisphere is more involved in analytical and sequential processing while the right hemisphere is more involved in integration and synthesis.'⁵⁹

Hence we have the fascinating phenomenon whereby the corpus callosum arises (relatively) late in evolution, but cannot keep pace with growth in brain size, and becomes actually smaller, in proportion to the volume of the brain as a whole, as evolution progresses. The number of callosal fibres gets proportionately smaller, both as the brain gets bigger,⁶⁰ and as it becomes more asymmetrical.⁶¹ In fact, as a general rule, the higher the species on the phylogenetic scale, or the more mature the individual organism, the more restricted the commissural connexions.⁶² And specifically in humans, there is a marked decrease in the rate of growth of the corpus callosum when compared with intrahemispheric white matter tracts, the long tracts that help draw together processes *within* each hemisphere.⁶³ (See Plate 3[a].)

The corpus callosum itself comes to embody the predicament of the entire cortex, and ultimately of the human world: how to hold things together, and yet keep them apart. Another theme of this book is the importance of union and division *together*.

Before we come to what this distancing of the hemispheres means for the human brain – because it has a very particular meaning and trajectory in man, which is of outstanding importance – let us look at how this intersects with a change that takes place in the other remaining axis, the front-back axis plane. And in doing so we need once more to come forward in time.

THE ANTERIOR-POSTERIOR AXIS

One of the differences between great ape brains, including human brains, and those of most other mammals is the expansion of the frontal lobes. In an intelligent animal such as the dog they account for about 18% of the brain; in monkeys about 30%; in the great apes about 35%, and in humans about 37% of the entire brain (the main difference between our brains and those of the other apes is that ours have more white matter – increased functional connectivity).⁶⁴ And what is the frontal cortex for? Largely for stopping things happening.

To members of a society in which doing things is much more highly valued than desisting from doing things this might seem paradoxical. Yet this negation is highly creative. It puts ‘necessary distance’ – in time and space – between ourselves and the immediacy of experience, so as to take the broader view, contextualise, test hypotheses and plan for the future. This enables us to stand back and see things in perspective, to choose whether or not to give in to the immediate reaction, or to see things in a different way, and respond more effectively; it enables us to delay gratification in order to achieve a greater end. It enables us to see our fellow creatures not merely as enemies but as potential allies; to see others, for the first time, as beings like ourselves, with needs and wants similar to our own. There is a proper distance between ourselves and the world which enables us to see what is going on: it is like trying to read a book – too close and one cannot see anything, too far away and one cannot make out the text. And this is true of all human experience, including those aspects that are, of all, the ‘closest’: our relationships with others we may love. They all require and benefit from necessary distance.

Thus if the relationship of the frontal and posterior cortex is antagonistic, yet it is in pursuit of the same goals. Negation is not by any means merely ‘negative’. Relationships can be understood only through images or metaphors, and the best one I know for understanding this particular relationship is the well-known one offered by Hegel. The bud gives way to the flower, which is the fulfilment, and yet the repudiation, of the bud; the flower gives way to the fruit, which is the fulfilment, and yet the repudiation of, the flower: and so evolution continues, constantly

‘negating’ (though not in any important sense truly denying the importance, or the meaning, of) the step that comes before it. This process, which Hegel refers to as *Aufhebung* (unhelpfully translated as ‘sublation’, and meaning something like ‘lifting up’, but also ‘suspending’, or even ‘transcending’), means the carrying up into a higher realm of something that is not, in truth, negated, but in fact fulfilled, by its own relinquishing of being *at that lower level*. Thus apparent opposites (according to the linear, left hemisphere way of thinking), elements in sequence, often turn out to collaborate in fulfilling their ends. Things and their opposites depend on one another for their being, bring about something new through their opposition, and ultimately co-create the world. They are dipoles.

In discussing what we think of as opposites I will frequently use the term dipole, which, according to the OED, is ‘a pair of non-coincident equal and opposite electric charges or magnetic poles ... an object, esp a molecule, atomic particle, etc, having such charges or poles’. Similar dipoles are threaded through the fabric of things.

Each hemisphere, of course, has its frontal cortex – but the distance from the world it offers will have a different purpose and effect in each hemisphere’s case.

Let’s take the right hemisphere first. If its *raison d’être* is to enable us to be on the lookout for potential predators, to form bonds with mates, and to understand, and interpret the living world around us, the role of the right frontal lobe is likely to be to provide the distance that enables us to do this more effectively. It will be involved (along with the posterior cortex of the same hemisphere) in everything that makes us, as Aristotle called us, the ‘social animal’. The distance it provides will stop us jumping to conclusions, for one thing: not all creatures are necessarily hostile or in competition, and distance enables us not just to bite. It must enable us to feel empathy, feeling our way into what it is like to be another; to interpret social signals such as humour or irony, oblique and intuitive signals from face and posture and tone of voice; and enable us to make sense of the world around us – to see the connexions. It must be able to integrate experience over time through memory. It must be in touch with reality here and now, as well as alive to one’s personal past and all that it teaches us. The right frontal cortex will facilitate the closest possible knowledge of the terrain. It will facilitate the human desire for exploration of the world. It will prove the seat of intelligent co-operation.

Similarly with the left hemisphere. If its *raison d'être* is to enable us to be effective predators, the role of the left frontal lobe is likely to be to provide the distance that enables us to do this more effectively. It will be involved (along with the posterior cortex of the same hemisphere) in everything that makes us, as Benjamin Franklin, the father of utilitarianism, called us, the 'tool-making animal' – manipulating the environment, hunting our quarry, getting what we need from it. It will enable us to hypothesise about the consequences of actions. It will develop emotional distance from the other: enable us to stand back and plan, to develop a strategy, to understand another's likely thought processes, not so much to empathise with, as to outwit, him. It will be focussed not so much on the past as on the future. In order to do this it needs to go 'offline', if you like, from the real world, and be able to consider various possible courses of action in a virtual fashion. For this, reality needs to be drastically simplified, 're-presented', rather than actually present (with all the obfuscating complexity that would bring with it): it needs to be *mapped*. The left frontal cortex will facilitate knowledge, not of the terrain, but of the territory. It will facilitate the human desire for exploitation, more than exploration, of the world. It will prove the seat of intelligent competition, rather than co-operation.

With the advent of language, especially, being able to go offline creates a relatively abstracted and virtual world alongside the immediate world of perceptual experience. And clearly they have to be kept apart and yet together if each is to work efficiently. Insufficient separation of function results in an impairment both of tasks preferentially undertaken by the left hemisphere and those preferentially undertaken by the right hemisphere,⁶⁵ but especially the latter.⁶⁶ In other words, given the opportunity, the left hemisphere's functions tend to dominate those of the right: the emissary usurps the Master.⁶⁷

The most ancient difference between the two hemispheres lies in two kinds of attention. And so does the most highly evolved difference, enhanced by the frontal lobes. The more focal attention is narrowed, the more it takes its object out of the realm of time, space, the body and emotion. A virtual world is merely the conclusion of that process – and that is where the evolution of the left hemisphere leads: to a *virtual* world. Quite how true this is will become apparent in the subsequent chapters of Part I.

SUMMARY

Asymmetry about its 3-D axes is a fundamental element of every nervous system, however ancient, of which we have knowledge. In mammals there have been changes in each axis that interlock with changes in each of the others. The corpus callosum, the band of fibres connecting the two hemispheres, which is peculiar to mammals, began by facilitating the working together of the hemispheres in sensorimotor tasks. As the brain grew larger, physical constraints on size required interhemispheric communication to be more selective, and hence impelled intrahemispheric specialisation in higher cognitive functions. The current role of the corpus callosum is at least as much to do with inhibition – keeping the hemispheres independent – as with facilitation – keeping the hemispheres working together. With the expansion of the frontal lobes and the invention of language, the need to pay the greatest possible attention to the world, on the one hand, and yet at the same time ‘go offline’ to manipulate symbols and data in a virtual world, on the other, has resulted in divergence of the hemispheres. As a consequence of this, as we will see in subsequent chapters, the right hemisphere is more in touch with reality, and the left hemisphere more concerned with the internal consistency of whatever virtual model of the world it happens to be working with at the time.

ATTENTION

Our world view is not simply the way we look at the world ... world views create worlds.

—*Richard Tarnas*¹

The question is not what you look at, but what you see.

—*Henry Thoreau*²

‘AS A MAN IS, SO HE SEES’, WROTE WILLIAM BLAKE.³ WHO WE ARE, THEN, determines how we see. And how we see determines what we find. Given that the hemispheres ‘see’ differently, how reliable is each hemisphere in its disclosing of the world? What elements does each contribute to reality?

One way to get a handle on this is to take a look at what happens when there is a degree of impairment in the functioning of one hemisphere at a time – either through illness, accident or temporary experimental inactivation. Damage to which hemisphere has the more catastrophic effect on our experience of the world?

In Part I, I will deal with hemisphere differences in relation to what one might call the ‘portals’ of access – ways in which we get a handle on reality. And in this chapter, I examine the all-important role of attention. Attention is not just another cognitive function. Attention is how our world comes into being for us. The altered nature of attention can appear to

abolish parts of the world, collapse time and space, eviscerate emotion, and render the living inanimate. It is a profoundly moral act.

Though attention and perception are importantly different, there is bound to be some overlap, since abnormal attention leads to abnormal perceptions, and vice versa. In turn perceptions inevitably involve making judgments. So this and the two succeeding chapters, on perception and judgment, should be seen not as entirely separate, but as one continuous process of helping the reader appreciate the extent and importance of hemisphere differences as they unfold before our eyes.

It is fair to say that, though the main deficits incurred by damage to the left hemisphere are in the twin important areas of the use of language and of the right hand, the world itself usually remains recognisable, and mainly, though not always wholly, undisturbed. That is because the right hemisphere is functioning as normal.

Things are very different when the damage is in the right hemisphere, and the subject is more – or wholly – dependent on the left. When those who care for left hemisphere stroke patients were asked to specify the most important problem encountered, they named difficulty writing or spelling; by contrast, when those who care for right hemisphere stroke patients were asked, it was loss of empathy. Almost half of carers for those with right hemisphere stroke reported as among the most important problems a whole range of cognitive and emotional impairments, as well as alterations to personality. Not one of the carers for left hemisphere stroke sufferers did so.⁴ For those with right hemisphere damage, they and their world had changed. For those with left hemisphere damage, they and their world were recognisably the same: it was their ability to handle it, to make use of it, that had altered.

As we have seen, the foundational difference between the hemispheres lies in the way they attend – and how you attend changes the world. It also changes you, the one who is doing the attending. Since it is of such consummate importance, let's take a closer look at attention from a hemisphere point of view.

The first thing to make clear is that there is a very substantial body of research over several decades indicating that the right hemisphere has by far the greater control of attention *in general*, as well as for switching attention.⁵ It is a familiar fact that, in right-handers, speech lateralises to the left hemisphere in almost all cases. What is not so well appreciated is that attentional dominance lateralises even more strongly to the right hemisphere than speech does to the left; and left-handers still display right-hemispheric attentional dominance in 81% of cases (a greater proportion than those still showing left-hemispheric language dominance).⁶

Obviously both hemispheres attend to the world and receive information principally from the contralateral attentional field; and we have already come across the difference in quality of attention in either hemisphere. It is well established that the right hemisphere has a special role in sustained attention and vigilance over extended periods of time.⁷ It is the right hemisphere, not the left, that in normal subjects maintains alertness during a task.⁸ But the right hemisphere can also attend in a focussed manner, characteristic of the left hemisphere, if required; whereas the left hemisphere cannot attend in the manner characteristic of the right hemisphere, even where necessary.⁹ Within the single left hemisphere, ‘it is not possible to have access to global and local information interactively.’¹⁰ When attentional demands increase, in whatever way, the right hemisphere tends to take over for the whole field.¹¹ Merely increasing attentional demands above the level of passive viewing – eg, a requirement to detect changes or discriminate complex forms – also increases involvement of the right hemisphere by comparison with the left, and in direct proportion to the demands of the task.¹²

In callosotomy patients, the right hemisphere is much better at sustained attention tasks,¹³ whereas the left hemisphere has a tendency to ‘space out’ for seconds (sometimes 15 or more) at a time.¹⁴ In a classic paper, Stuart Dimond wrote:

The performance of the left hemisphere is one full of gaps or holes, during which it is unresponsive to information presented from the external world. The left hemisphere is disengaged for what probably amounts to a large proportion of the time ... It may be that during these periods the left hemisphere simply falls inert and ceases to

retain its ‘awareness’, consciousness being diminished, but another explanation could be that ‘distractibility’ is a property of the left hemisphere ... The most striking phenomenon was the gap where ten consecutive signals were presented spanning a time interval of fifteen seconds and still the patient, although retaining completely adequate fixation, utterly failed to respond. Lapses of this duration were never seen on the right hemisphere but occurred with increasing frequency on the left.¹⁵

This is in a split-brain patient, granted. But nonetheless, following callosotomy, attention persists in the right hemisphere, ‘although somewhat diminished’, while the left hemisphere is ‘robbed of the power of concentration’ altogether.¹⁶ What happens to the world when the broad, sustained – and therefore sustaining – attention of the right hemisphere is compromised?

If attention grounds the world we experience, this difference should be of profound significance; to appreciate just how profound, read on.

We know that when we are highly focussed on a single aspect of a situation we can miss the most outrageously obvious events happening right under our noses. One of the most celebrated demonstrations of this is a short video clip called ‘Gorillas in our midst’, showing a basketball game in a relatively confined indoor setting.¹⁷ You are asked to count how many times one team passes the ball. When asked afterwards, most observers are completely oblivious to the fact that a figure in a grotesque gorilla suit walks into the middle of the mêlée, turns to face the camera, beats his chest with his fists, dances a jig, and strolls nonchalantly out the other side of the picture – something so comically blatant on second viewing, once you know what to expect, that it is hard to believe you could really have missed it. You were just too focussed on target. And research reveals that, when it comes to detecting unexpected change, the left hemisphere is relatively blind compared with the right hemisphere.¹⁸

A similar phenomenon can be demonstrated by another experiment, which has been often repeated. A stranger asks for directions from a passer-by and holds out a map. Two accomplices of the ‘stranger’, carrying a door (or something similar), walk between the two, and while the passer-by is trying to find where they are on the map, the stranger is substituted by one

of his accomplices. Most people, when they look again at the ‘stranger’, fail to notice the substitution, even when the size, age, hairstyle, race or even the sex of the stranger changes – or all of these.¹⁹ Focussed attention, the only kind the left hemisphere can offer, makes us blind to almost anything, however arresting and however close, that happens to be going on outside our sphere of concern at that moment in time.

But this is compounded by a second problem with left hemisphere attention. The right hemisphere is sensitive to the whole picture in space and time, background and periphery, while the left hemisphere is focussed on what is central in the field of vision and lies in the foreground.²⁰ This follows from the right hemisphere’s need to get a full understanding of the world, as far as is possible, while the left hemisphere needs to manipulate or grasp a prominent part of it. It is nonetheless quite a revelation to realise that so focussed is the left hemisphere on what it is up to, that it is content to ignore all that is irrelevant to its purpose – *grasping*; all that part of the world not available to its grasp, it leaves to the right hemisphere. As a result, when the left hemisphere is damaged, a whole world is still preserved by the intact right hemisphere; but when the right hemisphere is damaged, only the right half of the world remains, courtesy of the left hemisphere – in fact, ultimately much less than half, as we shall see.

Imagine, if you can, what life is like for a patient of mine who we’ll call Mike, an educated middle-aged man, an actuary, whose intellectual faculties are sharp. Since he sustained a stroke in the right parietal region, he lives in only half a world. Looking straight ahead, he is aware of everything to the right of him clearly, but of little or nothing to the left. Reading a book or newspaper, he seems to take in only the right page, or only the right side of the page, and ignore the rest. If I ask him to draw his house, he will draw the right-hand end only; when asked to draw a clock face, he will start off well, but approaching the bottom of the clock he will stop prematurely there at 6, or, if the numbers go on, allow them to spill out of the clock face down the right side of the paper. If someone stands to the left of him, he seems unaware that he or she exists. He behaves as if there simply is no left side to his body; he will wash and shave only the right half of his face. He eats all that’s on the right of his plate and leaves everything to the left, so that his plate has to be turned round by his wife.²¹

Surely there must be something wrong with his eyesight? No, his vision is fine: both eyes and his visual cortex and the tracts that connect them are

functioning normally. How can that be?

This curious state of affairs is a disorder not of the senses, but of attention, called ‘hemineglect’, or sometimes just ‘neglect’. Although the condition is a very common consequence of a stroke in the right hemisphere, it rarely follows one in the left: ‘most cases of right neglect [ie, following left hemisphere damage] resolve relatively quickly and the overwhelming majority of patients showing chronic bias has right hemisphere damage.’²² It can be reversed by global stimulation of the right hemisphere using a well-validated technique known as caloric vestibular stimulation, which involves irrigating the left ear with ice water.²³ As if to underline that the problem has nothing to do with eyesight, or indeed any of the senses, neglect of the left hemispace can be found in some form in all of the sensory modalities: sight, hearing, touch, proprioception (the internal sense of position and movement of the body parts), and even smell.²⁴ It leads to a failure to take into account half the world.

Incidentally, the case of the sense of smell is remarkable in a way that is highly relevant to the point I am engaged in making. While all the other sensory modalities are appreciated by the *contralateral* hemisphere (other side), olfaction alone is appreciated better by the *ipsilateral* hemisphere (same side) – ie, it doesn’t, at least initially, ‘cross over’.²⁵ Since the left nostril has little or no direct sensory input to the right hemisphere, and since it is the right hemisphere that is damaged, one might assume – wrongly – that left-sided olfaction would be spared. But that is, precisely, to misunderstand the nature of the problem: to see the problem as at a purely sensory level. The problem arises at the level of the whole world *coming into being* – or, as in this case, *not* coming into being.²⁶

Fig. 4. Drawings of the author, a flower, a clock, and a girl's face by patients exhibiting neglect. The girl's mouth suggests possible accompanying prosopometamorphopsia, another right hemisphere deficit condition (from clinical material of the author (1–3): fourth untraced)

This problem is exacerbated by the fact that the left hemisphere's attention is narrow at the best of times, even as regards its favoured right side of the attentional field. In normal subjects the extremes of space are supplied by the right hemisphere, even the extreme *right* of space.²⁷ So patients with neglect, secondary to a right hemisphere stroke or injury, also often exhibit not just a neglect of one half of the world, but simultaneously a narrowing of the window of attention paid to the part that remains.

And then there is a third problem. This concerns the fact that the right hemisphere's attention is maximally flexible, whereas the attention paid by the left hemisphere tends to be 'sticky'.²⁸ Following right hemisphere damage, particularly damage to the right parietal region, patients find their gaze pulled, despite themselves, towards the right – particularly towards static, inanimate objects in the right visual field – and they are unable to let go.²⁹ (Familiarity, instead of causing it to disattend, causes the left hemisphere to attend all the *more*). A patient of mine with a right temporoparietal lesion became fixated by screws in the hinges on his right when he was passing through a door, and would find himself stuck, staring at them protractedly, unless actively disengaged by one of his carers. (This also happens in schizophrenia: eg, one patient's main complaint was of

getting ‘fixed’ on items such as light switches, posters, radiator taps, fire extinguishers, houses at the end of a long row, other people’s left ears – always on the right side of his field of vision.³⁰) This abnormal fixation towards the right is not, however, itself the *cause* of visual neglect, because, remarkably enough, it is found in neglect patients when they are in a completely darkened room, where nothing is present that could attract and engage the subject’s attention, and asked to look for a non-existent visual target.³¹ Staring is a special kind of vision, in itself predatory: left hemisphere attention gets locked onto its target. As a result it more easily misses everything else.

This is yet further compounded by a fourth phenomenon known as the ‘attentional blink’. This refers to the fact that, after locating a target, there is a refractory period of usually between 200 and 400 milliseconds before one is able to register the next target. This is a normal phenomenon. But in hemineglect, and other right hemisphere deficit conditions where the usual counterbalance is lacking, attention is so ‘sticky’ that it takes about three times longer to disengage from the first target so as to spot the new one – which is therefore often missed.³² (Again, this aspect of attention is abnormal, too, in schizophrenia, being both prolonged and more extreme in effect than in normal subjects.)³³ As the researchers who discovered this noted, this means that visual neglect is a disorder of directing attention in *time*, as well as *space*.

And finally there is a further, fifth, phenomenon. It has long been debated whether we can conceive of, or, in a stronger version, even be aware of, things for which we have no words: the so-called, largely discredited, Sapir-Whorf hypothesis.³⁴ An interesting piece of research suggests that language does interfere with perception in the left hemisphere (the right visual field), but not in the right hemisphere (left visual field). The authors conclude that ‘it appears that people view the right (but not the left) half of their visual world through the lens of their native language, providing an unexpected resolution to the language-and-thought debate’.³⁵ If this is the case, it suggests that there may be still greater constraints on what the left hemisphere ‘sees’ compared with the right.

THE DISTINCTION BETWEEN ATTENTIONAL AND SENSORY DEFICITS

How a problem with attention differs from a problem with vision can be nicely illustrated. There is a condition, called homonymous hemianopia, in which there is damage to the optic tract, and here the patient becomes truly blind – not inattentive – to most of one half of the world. But if you compare a person with left homonymous hemianopia with one with left-sided neglect, the differences are marked.

The person with the hemianopia is only too well aware of what he is missing: the left half of the world still exists for him, he just can't see it easily. He turns his head so as to bring what he wants to see into the right field of vision. But not so with my patient Mike.

Compare these two exchanges, recorded by Georg Kerkhoff, one with a hemianopic patient and one with a neglect patient. Both patients had objective difficulties in reading as well as in visual exploration of the environment. First, the patient with the visual disturbance, homonymous hemianopia (HH):

Examiner: Have you noticed any changes in your vision since you fell ill [right posterior infarction]?

HH: Yes, my eyesight on the left is bad; and I can't read as well as I used to.

E: How would you describe your reading problem?

HH: It is just slower than before and more stressful. Sometimes I omit words at the beginning of a line. Often I realise it only when I get to the end of a sentence and it does not make sense. Sometimes when I get to the end of a line I can't find the beginning of the next. Or I skip a whole line.

E: Have you any other problems with your vision?

HH: Yes, sometimes I don't notice people on the left till too late, and then I bump into them.

E: What's your sense of direction like when you go out?

HH: It's bad, and when there's a lot going on it takes a lot longer for me to find things, especially when they are on the left.

Now compare with the patient with the attentional disturbance, neglect (N), answering the same questions:

E: Have you noticed any changes in your vision since you fell ill [right middle cerebral artery infarction]?

N: No, none that I know of. Except – there's something not quite right with my glasses.

E: Do you have problems with reading?

N: No, not really.

E: Do you sometimes miss words on one side of the page when you are reading?

N: No, I've never noticed that.

E: Have you noticed that your vision is not so good on one side, for example on the left?

N: My left eye is fine.

E: Do you sometimes bump into things on one side or overlook people on one side more often than you used to?

N: Well, sometimes I bump into things, true. But that is only because there's such a lot of people out and about – and people are so inconsiderate.

E: What's your sense of direction like when you go out?

N: I find everything that I want to find. ³⁶

There are a few things of interest going on in this second exchange, but for now, just notice that not only has something gone missing, but – its *lack* has also gone missing! The patient seems oblivious of his deficit. There is a pretty big 'unknown unknown' here.

Although patients with neglect are usually unaware of their problem, some do have partial insight. But this very insight, when it exists, also reveals an interesting sense in which a neglect patient differs from one with a visual impairment. Here is another patient with neglect, as reported by Peter Halligan & John Marshall:

I knew the word 'neglect' was a sort of medical term for whatever was wrong, but the word bothered me, because you only neglect something that is actually there, don't you? If it is not there, how can you neglect it? It does not seem right to me that the word 'neglect' should be used to describe it. I think they thought I was definitely, deliberately not looking to the left. I wasn't really ... If it is not there, you are not neglecting it. ³⁷

Just let that sink in for a second. What this patient is insisting on is extraordinary. At least for the left hemisphere, attention constitutes the world in a very literal sense: as far as your left hemisphere is concerned, what it no longer attends to is not just unseen, but *ceases to exist*. The left hemisphere, it seems, is a Berkeleyan idealist.

And indeed, as a general rule, when the right hemisphere sees a partially hidden figure, it can see the implied whole³⁸ – for it, the hidden part exists; meanwhile the left hemisphere sees only the fragment: for it, the hidden part just does not exist, and the implied whole disappears. The deceptively

simple image below says much about the problems encountered when seeing the world from the left hemisphere's perspective.

Fig. 5. Loss of the implicit in right hemisphere dysfunction. A triangle, resting on another, supported by six circles: in right hemisphere damage, the implied may become invisible, and the triangles are lost; there are only partial circles, half of which have protruding straight lines, like pincers, and half of which do not

Why does Mike not turn his own plate round, and eat what he must surely know he has left? Doesn't he remember that he encountered this problem yesterday, and the day before? He is, as I say, an intelligent guy. But for him the left side of his plate has ceased to exist. It isn't there now, and wasn't yesterday; it is not there – and *never* was there. There is a disorder of time as well as space.

ATTENTION AND DISORDERS OF TIME

In an important early paper, published in 1913, the Austrian neurologist Hermann Zingerle describes a 45 year-old clerk who had a stroke in the right temporoparietal region, resulting in neglect of the left side of space and of his body. 'His mood was often irritable, impatient, but generally cheerful, and he tended to be facetious', Zingerle begins, describing the mixture of jaunty insouciance and irritability typical of those with right hemisphere impairment. 'This was consistent', he continues, 'with the remarkable fact'

that he never mentioned his paralysis, disregarded it completely, and did not express any awkwardness about his handicap. He paid no attention to the left half of his body, seemed dismissive of it, and seemed to have completely forgotten about it. Even when his attention was drawn to his left side, he looked momentarily at, for example, his arm, and then took no further notice of it, and immediately began talking about something else. At the same time, he was quite aware that every person has a left and right side; he just didn't apply this to himself ... if one started to talk about the left side of his body, or asked questions concerning it, he suddenly went blank, and appeared obviously perplexed. He got embarrassed, made excuses, and became mute and inattentive; and it was impossible to evoke former memories of his left side. It was the same if the physician demonstrated the left side on his own body. The patient could recognise it: but this knowledge was irrelevant when applied to himself, and it did nothing whatever to prompt insight. If one persisted in trying to make clear to him the mismatch between his bizarre perceptions and the reality, by reasoning with him, or directing his gaze, he became more and more agitated, and there was no way he would come to an understanding. He was unaware of the oddity and absurdity of having only a right half ...

What Zingerle is pointing to is a failure of imagination (not fantasy, but imagination), the creative power that enables us to enter into what is there.

His patient can *no longer imagine – summon up – what it must be like to be different*. Despite ‘being able to perceive it with his senses’, he has lost, not just knowledge of the body now, but of it *at any time*, past, present or future:

not only has the patient lost the perception of the left half of his body, and knows nothing of his paralysis, he has also ... *forfeited the memory of the left half of his body*; both the perception and the previous knowledge of his left side were lost to him ... in his mind the representation of his body is apparently reduced to the right half, without any memory that this was once different.³⁹

Another patient of Zingerle’s

behaved in such a way as to make the greatest impression on all those present at the examination ... While he was able, despite his illness, to follow a conversation with concentrated attention ... *a sudden change came over him when he was asked to do anything involving the left part of his body*, or even if it were mentioned. Quite suddenly the patient would become completely unresponsive. He would gaze straight ahead without any sign of active attention, and showed no reaction, as if he could not hear, or understand what was required ... If he was asked to do something with his right side, he would always do so promptly ... In other respects swift to respond about his sensations, he could not be brought to say anything about his left side or to give an idea of his sensations on that side. Even insistent questioning, reinforced by shaking, resulted in a complete refusal by the patient. One could not get anything out of the same man who had moments before been talkative and attentive ... Whereas in relation to his right side he behaved completely normally, making appropriate use of it, reacting appropriately to all stimuli, and to questions about it, the left half of his body seemed not to exist for him ...⁴⁰

If, as far as the left hemisphere is concerned, the world exists only when that hemisphere pays attention to it, we have a problem, because its

attention is inadequate to sustain a coherent world, whether in space or time.

Let me make an analogy which (like all analogies) is certainly not an equation, but which will come, I believe, to seem more suggestive as Part I unfolds. The computer programmer knows far more than is in the computer, and is aware of that fact. The computer ‘knows’ only what the programmer puts into it. All else, as far as the computer is concerned, does not exist.

Unlike subjects affected by hemianopia, writes neuropsychologist Edoardo Bisiach,

neglect patients not only do not see stimuli presented in the contralateral half of space, but behave as if that half of space did not exist and never had existed. Indeed, the most astonishing aspect of neglect is perhaps this: patients suffering from it, not only are unable to perceive the left side of space, but are not even able to conceive it.⁴¹

The persistence of the world is guaranteed, it seems, only by the right hemisphere, rather as the persistence of unperceived elements of reality was guaranteed, in Bishop Berkeley’s philosophy, by their being present to the mind of God.

In illustration of Bisiach’s point, he and a colleague, Claudio Luzzatti, asked two patients with hemineglect to picture in their imagination a scene that was familiar to them – the main square in Milan, the Piazza del Duomo – as if they were looking toward the west front of the Cathedral, and to describe all that they could see.⁴² In this imaginary scene each patient was able to describe accurately the buildings that lay to the right along the south side of the square, but named in one case nothing, and in the other case almost nothing, that lay on the left. Later they were asked to imagine they were at the other end of the square, standing with the Cathedral behind them, facing the other way, and describe the scene in front of them. The patients now named the very places they had previously neglected but omitted those that had been previously recalled; only the buildings that lay along the north side of the square were now brought to mind. Even more astonishing, since neither had anything wrong with their memory, is the fact that they were not apparently dismayed by this in the least.

This finding is remarkable in a number of ways that have not always been appreciated. To begin with, it illustrates that attention is involved primarily not with seeing in itself, but – as far as the left hemisphere is concerned – with the bringing into being of the world, *seen or unseen*. We can see without attending and we can attend in the absence of sight.

Moreover, is it not strange that their recent experience just *disappeared*? These subjects are articulate people, in full possession of their faculties, as we would normally think of them, and they are not conventionally amnesic. How, then, can they not be aware of what it is they described only a short while ago? They can recall half the scene at one moment and the other half at another. Why can they not put the two halves together? It's like – why can't Mike turn his plate?

Various lines of thought converge suggestively. Some are already familiar to us: the right hemisphere integrates, while the left hemisphere fragments. Holding things together in space and time is how we bring a coherent world into awareness. What better demonstration can there be that, once the right hemisphere is compromised, the left hemisphere is incapable of putting the two parts of the scene together and seeing the whole?

But there are two further points worth making, while we are on the topic of time.

First, the fact of something coming and going from our awareness *necessitates* that it comes and goes from our awareness not just in space, but in time. If it is part of the living, embodied world, it is subject to time: outside of time it can have no embodied existence, and is purely an abstraction. An abstraction is neither permanent nor transitory. Whatever permanence, or transitoriness, a thing may have requires the presence of time (permanence is just when transitoriness lasts longer). Thus psychologist Cristina Becchio and philosopher Cesare Bertone posit that the key to the understanding of neglect is that it is a distortion of both space *and* time. As they put it, rather colourfully, this 'temporal distortion results ... in an ontological landslide, sweeping away the left side of the world'.⁴³

Second, it so happens that the right hemisphere is the source of our sense of time, as something lived through, as having duration (what Bergson called *durée*, in contrast with *temps*).⁴⁴ This is precisely what we would expect if the right hemisphere deals with the sustained continuity of real experience – where everything that happens, happens in the flow of time – and the left hemisphere with a comparatively abstract realm,

snapshots taken out of the flow, beyond the real-world context of actual, specific, existing beings that are subject to change.

What do we know of the role of the right hemisphere in understanding time? The right hemisphere is generally superior at estimating time intervals.⁴⁵ The integrity of the right hemisphere is critical for temporal reproduction of intervals longer than a couple of seconds.⁴⁶ And, while damage to the right hemisphere impairs estimation of time duration, it does so particularly drastically in patients with neglect.⁴⁷ This is consonant with the interesting finding that normal subjects show increased sensitivity to the duration of events that are presented in left visual space, the right parietal cortex being dominant for temporal integration.⁴⁸ Right frontal damage also impairs estimates of duration,⁴⁹ and indeed a network involving both prefrontal and inferior parietal areas in the right hemisphere seems to be responsible. In a study directly comparing those with right and left hemisphere damage, of those with time disturbance, 100% had right hemisphere damage involving those areas; subjects with lesions in the corresponding areas on the left showed no deficits of time appreciation whatever.⁵⁰ Neuroimaging in normal subjects demonstrates increased activity in right hemisphere frontal and temporal regions when individuals attend to the passage of time.⁵¹

Stephen Wolkind, Alwyn Lishman and I reported the case of a 23 year-old woman with Tourette's syndrome with severe impairment of every aspect of time appreciation, including complete inability to assess time duration, assess an appropriate time for her baby's feed (despite being a very concerned mother), or keep to time for appointments.⁵² She was fully disorientated in time. Despite normal full-scale IQ, she seemed cognitively out of tune with time: she thought that there were 10 seconds in a minute and 24 minutes in an hour, and could not rehearse the sequence of the months correctly. She had a complete inability to read a clock face, and, in drawing, filled in the figures on a clock face backwards. She was unable to distinguish between periods of weeks, months and years, and had a distorted chronology of her own life: in giving dates from her personal history she was either incorrect, sometimes by as much as five years (remember she was only 23, so five years is a long time), or used vague phrases such as 'a lifetime ago'. We termed such an extreme and global inability to appreciate time *dyschronia*. Patients with Tourette's show

evidence of right hemisphere deficits (this patient showed evidence of mild volume loss in the right hemisphere).⁵³

So important is the right hemisphere for time perception that not only does the capacity to assess the passage of time worsen after right temporal lobe excisions, but it may actually improve after left temporal lobe excisions.⁵⁴ Damage to the right hemisphere is responsible for almost all abnormalities of time perception. There is something called the *Zeitraffer* phenomenon, in which events appear to change speed, and often lose their fluidity of motion (the German name refers to time-lapse photography). The phenomenon was investigated by John Cutting, who remarks on the aptness of the term since subjects ‘may also experience movement as jerky and discontinuous’.⁵⁵ He could find 13 cases in the neuropsychological literature, all of which had right hemisphere damage, none left hemisphere damage.⁵⁶ Fred Ovsiew reported a further case with right temporal damage, and his literature review found the right hemisphere preponderance to be ‘striking’.⁵⁷

There is a slightly different condition, palinopsia (from Greek, *palin*, + *opsia*, ‘seeing again’), also sometimes called akinetopsia (*a*, + *kinet*-, + *opsia*, ‘seeing no motion’). In this condition movement can appear dislocated as if in a juddering ciné film and there is persistence of after-images (see Plate 3[b]). It has been described, according to an extensive survey, ‘much more frequently with right-sided than left-sided lesions’ (typically in the parietal or parieto-occipital region).⁵⁸ In his monograph on palinopsia (which he originally termed ‘paliopsia’), Macdonald Critchley described a case he considered typical, of a man with a gunshot injury to the right occipital region.⁵⁹ The subject found that when he focussed upon anything he felt his gaze pulled towards the right and a stream of static images replaced the flow of movement: ‘the various images were arranged in parallel series, close to one another, and they were all of the same size’, like an old reel of film getting stuck.⁶⁰

The overlap between the *Zeitraffer* phenomenon and akinetopsia is considerable: akinetopsia, too, is almost always consequent on right hemisphere (or bilateral) damage.⁶¹ In a series of 12 patients the disturbance could be localised to the right hemisphere in 10, or possibly 11, cases, and in only one to the left;⁶² another reported that 12 out of 14 palinoptic patients had right-sided lesions;⁶³ in two series of 3, all 6 cases

were right-sided.⁶⁴ Another survey by David Gersztenkorn & Andrew Lee, which claims to cover every case reported in the literature, revealed 45 that followed identifiable localised brain pathology: of these all but nine had right-sided lesions.⁶⁵ (Unfortunately the authors do not report handedness. They also appear to have overlooked the cases reported by Kömpf and colleagues in 1983, both involving right occipital lesions; the case reported by Arai and colleagues in 2002 which involved a right falcomeningeal meningioma; and two of the three cases (cases 7 & 9) of palinopsia reported by Landis and colleagues, in which the lesions were right temporo-occipital and right parieto-occipital).⁶⁶ In Macdonald Critchley's monograph on the condition (also overlooked by Gersztenkorn & Lee), of the five cases where localised brain pathology was verified, only one did not involve the right hemisphere. In one case report, a woman described seeing the smooth movements of people

as a series of discontinuous 'freeze frames'. The opening of a train door was 'broken up' and those nearby appeared to 'move in slow motion'.

There were recent infarcts in the right inferior parietal lobe and parietal-occipital junction; none was detected in her left hemisphere.⁶⁷ John Cutting reports a patient with right hemisphere damage who experienced time as 'a sequence of snapshots'.⁶⁸ I have reported other evidence elsewhere, and will discuss a particularly significant case of 'freeze frame' or 'stop-go animation' in a later chapter.

Right hemisphere damage leads, then, to impairment in the perception of temporal flow. And, importantly, the right hemisphere has a longer working memory, so that it is better able to *maintain* in awareness what is attended to over time. Take that away and our experienced reality may fragment.

It is from motion that we gain our sense of both space and time. The right hemisphere seems to be essential for both, and the capacity for each is linked with the other.⁶⁹ The left hemisphere's focus, however, narrows both. If I want to focus precisely on a particular element in my environment, clearly and in sharp detail, I have not just to home in on it in space, but to immobilise or freeze it in time, too. It becomes like a snapshot (what the

French call, suggestively, a *cliché*). The more precise anything is, the less content it has: ‘the more certain our knowledge the less we know.’ The left hemisphere’s experience is fragmentary and therefore taken out of the flow of experiential life, and tends towards stasis. It is concerned with the moment of the ‘kill’. However, outside of this glare of the spotlight, things carry on living, moving and changing.

While the right hemisphere gives the sense of duration, the left hemisphere is able to tell which of two sounds came first: whether it can do so better than the right hemisphere is uncertain, and the evidence is inconclusive.⁷⁰ At any rate, its processing concerns the comparative positioning of points (whether in space or time), rather than the continuous extent or *depth* of the medium; it cannot deal with the extended, continuous flow of time. Similarly, the left hemisphere can tell that a *point* in space is above or below, to the left or right of, another one, but as to actually where in the continuous field of space it is – how far away it is, how high above the other point it might be, and especially anything that implies the capacity to see depth – that depends almost entirely on the right hemisphere.⁷¹

Neuroscientist Jake Jordan notes the ‘striking lateralisation’ of function in the hippocampus in rats. His research suggests that ‘the left hemisphere stores spatial information as discrete, salient locations and that the right hemisphere represents space continuously, contributing to route computation and flexible spatial navigation’. This is a crucial insight into the way in which the right and left hemispheres differ in their understanding of time, space and motion.⁷²

ATTENTION AND DISORDERS OF SPACE

We have considered the phenomenon of spatial neglect. But are there other changes to the nature of space – as distinct from perceptual distortions, which form the subject of the next chapter – that characterise damage to one hemisphere?

The right hemisphere tends to present the world in three dimensions, with volume and depth as we experience it. In the left hemisphere's version of the world, however, both space and time seem to lack depth.⁷³ Space becomes relatively flattened and schematic, time tends towards a point, or points. After commissurotomy, the right hand gets input only from the left hemisphere, and as a result it can no longer draw a cube in perspective. The hand that all its life has been drawing cubes is now suddenly incapable of doing so: it produces something that looks like a child's flattened cube, an attempt to show all the surfaces in one plane. The left hemisphere, in other words, draws the 'theory', or idea, of a cube, what we *know* (that the cube has six sides), not the actual cube we *perceive* by paying attention to it (which has at most three surfaces visible, and at most one of them rectangular). Meanwhile the left hand of the split-brain subject still has input from the right hemisphere and, even though not practised at doing so, continues to be able to draw a cube in perspective.⁷⁴ Below are examples of copying a simple figure with the left or right hand in a subject five months after commissurotomy.⁷⁵

Fig. 6. Commissurotomy patient five months post-op, copying a model with either hand (from Bogen 1969: detail)

Disturbance of visual depth perception can also be observed in stroke patients. In 1935, Hans Hoff and Otto Pötzl reported two cases showing a foreshortening of visual depth: both were due to right-sided brain insults, one in the right intraparietal region and the other in the right occipital ('calcarine') region.⁷⁶ In experimental suppression of the right hemisphere, Nikolaenko found that in the left hemisphere objects are 'represented as if they were seen in the *distance*, in a *plane*, *bodiless* and *generalised*'; the left hemisphere tends to re-present the visual world as not just flattened, but as abstract and schematic.⁷⁷ Additionally objects become stylised, symbolic, 'geometricised': a tree becomes a stick, or a Y; a flower becomes a circle like a button with regular segmentations to denote petals; a person becomes a pair of rhomboids, one on top of the other, or a stick man.⁷⁸ Because of the relative difficulty involved for the left hemisphere in assessing depth, it may get the size of objects notably wrong.⁷⁹ The flow of life is lost. By contrast, the drawings of the isolated right hemisphere are recognisable three-dimensional, living, flowing forms, though they may lack detail.⁸⁰

A striking experiment by Ramachandran and colleagues demonstrates how an attentional defect – in this case, neglect – wholly alters the subject's very sense of reality:

Contrary to what the term ‘neglect’ implies, the syndrome must surely involve much more than simply ignoring the sensory input from the left side of the world. To explore this experimentally, [we] recently asked a patient to turn her head to look into a mirror hanging on her right – parallel to the sagittal plane. Standing on her left (neglect) side, I then showed her a candy-bar, the reflection of which was clearly visible to her. Remarkably, instead of reaching leftward to accept the candy, she repeatedly reached into the mirror – even though she knew it was a mirror – complaining all the time that the candy was beyond her reach. (Another patient even tried reaching behind the mirror!) Thus, even the patient’s ability to make rational deductions had become selectively distorted to accommodate the strange new sensory [or, as I would say, attentional (IMcG)] world that she now inhabits.⁸¹

The right hemisphere of normal subjects can be temporarily, experimentally, suppressed. Both depth and perspective, as if by a stroke of magic, are suddenly diminished or lacking altogether.⁸² Patients with right posterior stroke may experience a complete and disconcerting loss of depth perception resulting in ‘flat vision’, as if all existed on the plane of a screen at a certain distance away from the subject: an IT fantasy.⁸³ Patients with right, but not left, hemisphere damage cannot infer three-dimensional structure from motion.⁸⁴ All in all, it is the right hemisphere that underwrites our sense of the depth of space, time and –motion.⁸⁵

ATTENTION AND DISORDERS OF MOTION

Motion is flow in space and time.

Some exciting new research confirms how important it is to think in terms of a whole hemisphere, not just a module (or still worse not to investigate or report hemisphere differences at all). It concerns the topic of motion perception. The research demonstrated, first, which is interesting in itself, that patients with a right temporal visual lesion found it difficult to perceive central motion, regardless of form or speed, or to infer three-dimensional structure from movement, while those with an equivalent left-sided lesion were unaffected. So far, so familiar: without the right hemisphere's input, the left hemisphere's central field becomes motionless, much as expected. But hitherto motion perception had been thought to rely on a specialisation in the parietal cortex only. 'This dramatic finding', according to the authors,

*indicates that motion-sensitive areas of cortex by themselves do not suffice for normal motion perception and that additional cortical regions are required ...*⁸⁶

This might not sound that significant. But the import of this is that to assess and to *understand* motion, even of the most simple kind, involves other aspects of perception, and depends not on just one or two local 'components', but on the concerted action of broad areas of integrated right hemisphere cortex, including, in this case temporal, cortex. What that means is that motion is not just another accidental characteristic, like being blue or round, but is foundational in some deeper way. (I will argue that, along with time, with which it is intimately related, it is, in fact, foundational to being: see Chapter 23.) The lesson is that thinking in terms of large integrated networks within a hemisphere may reveal what focus on narrow regions of interest (ROIs) cannot.

While it is generally accepted that the right hemisphere is responsible for our sense of time, and that damage to it causes alteration of the speed of perceived motion, *both* acceleration and deceleration have been reported. Clearly both do occur, and the situation is usually left at that. But can we be

more precise about what is happening? It might reveal something of interest.

In the first place, if your sense of time slows way down, will not the motion going on around you (that you are not focussing on, or part of) appear unreasonably speeded up? And, in the second, if the stabilising, integrative effect of the right hemisphere across the world of experience is lost, won't the attentional field separate out into two relatively distinct realms, one at the focus, where the left hemisphere dominates (no longer moderated by the global concern of the right), and where everything is *slowed down*; and one at the periphery, where in as much as things are perceived at all, they are indistinct and, by comparison, seem *speeded up*?

Some of the evidence certainly suggests that this is precisely what happens. Here is a report of a man who suffered a right hemisphere stroke, in which both stasis at the focus, and speed at the periphery, are exaggerated. A 62 year-old man in a Viennese café experienced a 'strong attack of vertigo':

as he attempted to cross the street, he thought that cars were rushing towards him from the right and left. When he looked back towards the cars, he noticed they were not moving so quickly; on the contrary, it seemed as though the car he had just fixed his eyes on was now moving very slowly. He took two steps back from the curb and noticed pedestrians moving quickly toward or away from him. He called out to one pedestrian who approached him and he had the impression that he was slow to come to his aid ... in a taxi he noticed that everything within range of his vision was occurring in accelerated motion. It did not occur to him [then] that in the centre of his visual field he was seeing things in slow motion ... On another occasion, the nurse and doctor who were summoned moved so quickly that the patient became 'dizzy'. When he then looked directly at these quickly moving figures, which he did only with difficulty, the figures seemed to remain still ... He noticed that an intense noise – like the crackling of a motorcycle – forced an acceleration in the periphery and a central deceleration. When he looked out the window, pedestrians in the outermost field of vision seemed to be moving at a speed of about 40 kilometres per hour ...

objects that were fixated, eg people, were moving along ‘as in a funeral procession’.⁸⁷

This case was reported by the early twentieth-century neurologists Hoff & Pötzl, who refer to two cases with similar combinations of deceleration at the centre and acceleration in the periphery of the attentional field.⁸⁸ Since this is an attentional problem, not a problem with the visual system, it could occur in any sensory modality; in the case above this seems to happen both visually and aurally – with the sound of a motorbike, for example. As if to make the point, another patient, also with a right hemisphere stroke, displayed the same phenomenon in sound. When people spoke to him directly it was always at normal speed and quite clear, but when they talked among themselves he wondered ‘why they were trying to set a record for speed-talking, and how they managed to do it’.⁸⁹

Here is a more recent description, in the most striking terms, of the experience of a right temporal stroke:

I vividly remember looking up at the showerhead and having the perception that time had slowed. The water stream from the showerhead separated into droplets as they moved away from the head (that was normal and real) and I recall seeing the drops seemingly hang in mid-air but I don’t recall them stopping. The effect was very similar to the way the bullets travelled in the Matrix movies, minus the trails that the special effects crew added behind the bullet. I don’t recall any trails behind the water droplets, though that may be a failure of my memory. I remember the scene being very clear. I noted to myself at the time that I could see every droplet clearly when you’d normally perceive the streams as more of a blur of movement. I can’t remember if I saw them speed back up afterward, though I have a vague notion that they did while I was looking ... As I think about it, it seems a good way to describe it is that the water droplets went into sharp focus as they slowed down, but I’m unclear how the event resolved itself.⁹⁰

This beautifully describes left hemisphere vision: at the centre of the field, the world is extraordinarily precise and almost motionless, and,

although he cannot be sure in reporting this, his impression is that in the periphery it regains speed and indistinctness. Flow is suspended.⁹¹

This makes a fascinating contrast with neuroanatomist Jill Bolte Taylor's experience of a *left* hemisphere stroke while having a shower (thus releasing, instead, the right hemisphere's take on the world). She describes how she 'reeled backward in response to the augmented roar of the water'.⁹² In the right hemisphere, then, flow is, by comparison with the normal situation, enhanced.

Another early Austrian paper, by a colleague of Pötzl's, Ernst Pichler, reports four cases of right hemisphere damage, three with alterations of time perception. One subject with right parietal damage reported seeing people move 'as if in a slow-motion sequence from a sports film'.⁹³ Another, with more diffuse right hemisphere damage, complained that 'the people who went up and down in the room – mainly nurses – moved abnormally quickly, so that he could scarcely follow them with his eyes ... [at the same time] he had the feeling that time stretched out endlessly.'⁹⁴

Another patient – this time from the classic series of the pioneering neurosurgeons Sean Mullan and Wilder Penfield – with a right hemisphere glioma, a brain tumour, had the illusion that if she was looking directly at moving things or persons, they slowed down, and

were extremely well defined and conspicuous, and almost [de]composed into their different parts. She compared the illusion to 'a movie going slow motion' ... If she was looking at an immobile object, it appeared as though it were 'still more fixed.' Her surroundings seemed to be at 'double standstill'.⁹⁵

Notice the decomposition into parts, and being 'well defined and conspicuous', two further indicators that this is left hemisphere attention. A different patient from the same series, with a right temporal glioma, had similar experiences:

visual illusions of slow movement, increased fixity of the immobile objects and increase in visual detail (e.g., in one attack, looking at her hands, she observed that the skin pattern was extremely well defined).

Once again the very clear visual detail at the focus of attention, combined with the illusion of fixity, suggests that the deficit due to the right hemisphere tumour has given rise to an exaggeration of left hemisphere attention.

The study on motion perception earlier reported is relevant here: patients with a right-sided, but not with a left-sided, lesion in the ventral visual pathway displayed widespread impairments in central motion perception.⁹⁶ This is in keeping with an earlier study reporting that only right-sided lesions caused difficulties in processing visual motion.⁹⁷ An unusual case of a patient who was actually *motion-blind*, reported by Josef Zihl in 1983, had bilateral lesions, though on re-examination by Zihl and others in 1989 it was reported that the principal lesion was right-sided.⁹⁸

Right parieto-occipital lesions, then, cause deficits of visual depth perception, time perception and motion interpretation.⁹⁹ An epileptic focus can sometimes lead to an exaggeration of the normal activity of the affected cortical area. A patient with a left hemisphere epileptogenic focus found that everything in the visual field to the right, the left hemisphere's priority, seemed to grind to a halt: 'the patient reported that there was no motion of objects seen within the [right] visual hemifield affected'. After surgery, objects were no longer stationary, but they continued to slow down as they moved into the right visual field.¹⁰⁰

Disturbances of motion are rare after left, as opposed to right, hemisphere brain damage, but when they do occur, they are the reverse of what has just been described: the *centre* of the field of vision now seems not slowed down, but speeded up, since the Gorgon is no longer operative. A patient with a left frontal lesion reported that 'external objects seemed to be rushing toward him at an incredible rate ... He complained that he could no longer tolerate watching television, because the progression of events was too quick for him to follow'.¹⁰¹ It is like Jill Bolte Taylor's 'augmented roar' after her left hemisphere stroke.

In passing I should mention that the idea of a fixed stare (of the Gorgon, or of the basilisk, for example) that immobilises and kills is embedded in the mythology of, certainly, Western cultures going back to the Minoan civilisation. It is also relevant (a topic that I have explored elsewhere) that when we find ourselves to be objects of attention, we respond to the quality of attention to which we are subjected, and experience ourselves as transformed by it: when we are stared at, we feel ourselves *immobilised*,

which is perhaps why prey seem – and indeed are – transfixed, as we put it, by their predators.^{[102](#)}

It seems then that the left hemisphere world lacks some pretty important aspects of reality – those to do with time, space and motion. How real, in other respects, is the world generated by the left hemisphere?

ATTENTION AND DISORDERS OF EMOTION

Let's go back to Zingerle's patients a moment. The attitude of these right hemisphere stroke patients to what has happened is frankly bizarre. As far as they are concerned, their left half has just gone missing: they are likely to be partially or wholly, paralysed on one side. Yet their attitude seems inappropriately lacking in affect, in *depth* – not depth, here, in space or time, but *emotional* depth. Take another example, that of a patient who, following a right hemisphere stroke, developed an 'extra' hand and part of an arm, and who seemed generally somewhat depressed:

However, when speaking of the 'extra' hand she would become gay and bantering. If she were unable to 'find' it she might remark: 'Oh, it will turn up after a while, just when you don't want it.' When asked if the arm had changed at all she replied, 'No, just as heavy; it's a nuisance – why don't you take it home with you? I'd like to know what your wife would say. You'd really have to make up a story!^{[103](#)}

Such patients are either irritable, inappropriately jocular, or totally unresponsive. Remember the muteness that Zingerle's patient displayed. It is known for patients, whose speech is otherwise normal and not in any way affected by the stroke, to become mute, or for them even to utter pure gibberish – but only so long as their attention is drawn to the left side. Otherwise it is normal.^{[104](#)}

Although the muteness has a defensive feel, it goes well beyond a reluctance to deal with a painful topic. Sometimes neglect has, indeed, been framed as a form of denial, in the Freudian sense of the repression of unwanted knowledge about a handicap. But patients with a left hemisphere stroke, whose right hemisphere is therefore intact, complain, understandably and sometimes bitterly, of their handicap, often having severe emotional reactions. Those with right hemisphere strokes as a rule do not. And indeed the second patient of Zingerle's ('Case III') that we referred to did not even have a paralysis: so his odd detachment cannot be

accounted for on the basis of shame about, or fear of, losing the use of a limb.

As I hinted, in the report of Bisiach and Luzzatti one of the two subjects did mention a couple of prominent items from the neglected side in one of the trials. But as so often it is not just *what* was done, but *how* it was done, that matters. The authors noted a curiosity: ‘while central and right-sided items were enumerated in a rather lively manner and sometimes dwelt upon, the few left-sided items were mentioned in a kind of *absent-minded, almost annoyed* tone’.¹⁰⁵ As if dismissive.

Then, remember the patient of Kerkhoff’s? As he says, neglect patients have a tendency to give answers that are ‘vague, inappropriate and beside the point’:¹⁰⁶

E: Have you noticed any changes in your vision ... ?

N: No, none that I know of. Except there’s something not quite right *with my glasses* ...

E: Have you noticed that your vision is not so good on one side, for example on the left?

N: *My left eye* is fine ...

N: Well, sometimes I bump into things, true. But that is only because there’s *such a lot of people* out and about – and people are so *inconsiderate*.

At first all is fine: the patient has no problem (nothing wrong with his eyesight, just with the glasses). Then there is what looks like a deliberate evasion: when asked about his vision on the left, he replies that his *left eye* is fine – which has the virtue of being true, but is beside the point, because his left-sided vision is patently not. And then notice that, to the extent that a problem *is*, to any degree, admitted, it is clearly someone else’s fault. There are too many people and *they* bump into *him* because ‘they are so inconsiderate’. And his last answer, ‘I find everything I want to find’, seems

defensive, as though he knows there is something wrong, but can't admit it, even to himself.

These patients exhibit not just neglect, but what is called anosognosia (Greek *a*, not, + *nosos*, disease, + *gnosis*, knowledge), unwillingness to acknowledge a deficit, as we have noted. This is almost always consequent on right hemisphere damage.¹⁰⁷ This might sound like a simple cognitive problem, a neglect of information, rather than, as it is, a denial of experience. There is not just a derangement of cognition (knowledge about), but of affect (emotional involvement with), known as anosodiaphoria (Greek *adiaphoria*, indifference).¹⁰⁸ Of a patient who had just had the right hemisphere of his brain removed, his clinicians noted, 'we were surprised to find a man who could discuss his condition in a seemingly detached and objective way. Our surprise was shared by most other people who met the patient.'¹⁰⁹ Another referred to his paralysis in 'an almost facetious manner', and 'throughout the consultation, he cheerily and light-heartedly bandied small talk with his doctors'.¹¹⁰ A 40 year-old woman with a right parietal tumour reported that she was 'half a woman' and that her left side was dying away. At the same time she was euphoric, displaying a complete lack of concern, and what is described as a '*j'm'enfichisme total*': she absolutely couldn't care less.¹¹¹

Including about the truth: there is a strong tendency to disown problems, fail to take responsibility, and to maintain to the last that it is 'nothing to do with me, guv'. The right hemisphere-damaged, left hemisphere-reliant, patient is always in the right.

A colleague told me the story of one of his neglect patients, who had hit his car on the left side no less than six times while driving it into the garage. 'My garage was designed by a friend who is an architect', he said. 'Some "friend"! He has come back and changed the size of the garage entrance without telling me. Now I see who is my "friend". And to think – for so many years he was just pretending to be kind to me'.¹¹²

This disowning has its roots in a disconnect between the perceived outcome and the conscious will. The left hemisphere's is the wilful consciousness, the one that makes things happen. Its purpose is clear: action towards a target that is centre-stage, taking possession of what is in full vision. But unfortunately it knows remarkably little about all the rest. So when things outside its ken happen, they logically *must* have been willed by someone else. They are someone else's responsibility. This is why

schizophrenia, a condition which mimics right hemisphere damage in many respects, is characterised by what are known as ‘passivity phenomena’: the sense that thoughts, actions, feelings and even moods, that come from the unconscious mind, or at least from the periphery of consciousness, are caused by someone else. They have not been integrated into the self: for that to happen a properly functioning right hemisphere would be required. They become instead a trigger for paranoia: who are these mysterious malefactors?

As if to confirm this, the reverse happens in depression. Whereas in schizophrenia the right frontal lobe is underactive, and responsibility for one’s own thoughts, actions and mood is not accepted but projected outwards onto others, in depression the right frontal lobe tends to be relatively overactive compared with the left; subjects are *over*-willing to accept responsibility, even taking responsibility for things they could have nothing to do with. A patient of mine, a middle-aged doctor, believed he had caused the war in Bosnia; and depressed individuals have even been known to present themselves to the police, demanding to be arrested for the terrible crimes which (they say) they have committed. The right hemisphere is the most important mediator of our empathic, other-connected, responsible – more selfless – self. The German psychopathologist Werner Scheid spoke of the ‘pointer of guilt’ [*der Zeiger der Schuld*], that points in the centripetal direction in depression, whereas a paranoid psychosis must be assumed when it starts pointing in a centrifugal direction towards others.^{[113](#)}

How far can disowning be taken? Well, let’s have a look. The first of Zingerle’s patients insisted that

on his left there was someone lying in the bed – a woman – at which he pointed to his left side, and could not be dissuaded of this even when he inspected the area ...

He complained about her spoiling his sleep. So his arm belonged to a woman who happened to be in his bed, and disturbed his nights – and that was that. He said all this in a wholly inappropriate, jokey fashion, meanwhile erotically caressing his left arm.^{[114](#)} That’s disowning good and proper: ‘Not a little-place-at-Tooting, but a country-house-with-shooting

and a ring-fence-deer-park Lie!’ Except it isn’t strictly a lie, as I shall explain. He exhibits a further, decidedly odd, phenomenon called somatoparaphrenia (Greek, *somat* -, body, + *paraphrenia*, madness) – a conviction that part of one’s body belongs to someone else. Such cases are far from unusual in right hemisphere damage.^{[115](#)}

ATTENTION AND CONFABULATION

If you don't know how to explain something, why not just make it all up? Welcome to another important feature of the left hemisphere's world: confabulation.

Confabulation means the invention of a story to fill in a gap. It is not the same as lying. In lying we are conscious of the deceit; in confabulation the subject believes the story. I can't remember where I was yesterday, so, instead of saying I don't know, I make something up: 'I was working in a jeweller's shop', as one of my patients confidently informed me (in reality, he had been on the ward all day; he had worked as a postman in Cardiff, and his wife confirmed he had never worked in a jeweller's shop in his life). There is no shame involved and no sense of whether the story is plausible:

Pressed to justify their judgments, the patients were often illogical and oblivious to self-contradiction ... Patients who were inconsistent usually offered an irrelevant comment or said nothing when the examiner pointed out the inconsistency. *No patient ever showed embarrassment.*¹¹⁶

So confabulation has two characteristics that make a thought-provoking pair: when it is the consequence of right hemisphere dysfunction, the confabulated story is often implausible, but is held with total conviction, not in a tentative, 'oh well, I suppose I must have' sort of way. And, while confabulation can happen in a range of conditions, including sometimes after left hemisphere damage, it is much commoner after right hemisphere damage, when it is also more florid, and more incorrigible.¹¹⁷ In fact it is a bit of a left hemisphere specialty.¹¹⁸

The neuropsychologist Michael Gazzaniga calls the left hemisphere 'the interpreter', because, he says, it makes up the stories that fill in the gaps. The trouble is that when it hasn't got a right hemisphere to help it out, its assessment of what is realistic is not what it should be. In a recent book, he writes:

Though the left hemisphere had no clue, it would not be satisfied to state it did not know. It would guess, prevaricate, rationalize, and look for a cause and effect, but it would always come up with an answer that fit the circumstances. In my opinion, it is the most stunning result from split-brain research ... The right hemisphere does not do this. It is totally truthful ... [119](#)

On this, a brief diversion. A famous example, reported by Gazzaniga and his colleague Joseph LeDoux, illustrates the point. It is important to understand that this involves a split-brain patient.

The experimenters show him a picture projected to one or other hemisphere on its own and ask him to pick a card connected with the scene. For example, they show a snow scene to the right hemisphere and ask him to choose an appropriate picture from an array of cards, with either hand. He cannot *say* what it is that he has seen, because only the right hemisphere saw it, and the right hemisphere cannot speak; but his left hand, controlled by the right hemisphere, is able to go straight to the picture of a shovel. However, since the left hemisphere did not see anything at all, his right hand chooses at random, and scores no better than chance.

Then the experimenters make things a bit more interesting. At the same time that they flash a picture of the snow scene to the right hemisphere, they flash a picture of a chicken claw to the left hemisphere. Because the hemispheres are disconnected, each hemisphere has knowledge of only one image, and in each case it is different. When they ask him to choose an appropriate card, again his left hand chooses a shovel (because the right hemisphere has seen the snow), but the right hand chooses a picture of a chicken (because on this occasion the left hemisphere saw a chicken claw). When asked why his left hand had chosen the shovel, his verbal left hemisphere, which has to respond to the question, but knows nothing of the snow scene, the real reason for choosing the shovel, is not in the least abashed. He confabulates, explaining that he saw a chicken, ‘and of course chose the shovel because “you need that to clean out the chicken shed”’.

Not so much chicken shit, but another kind springs to mind...

The really interesting finding here, as the authors themselves put it, is that ‘without batting an eye’ the left hemisphere draws mistaken conclusions from the information available to it and lays down the law

about what only the right hemisphere can know: ‘yet, the left did not offer its suggestion in a guessing vein but rather [as] *a statement of fact*’.¹²⁰

A rather nice – now classic – piece of research may exhibit both the left hemisphere’s tendency to grasp and its tendency to confabulate. Asked to choose tights from an array of four on a line (all of them in reality identical), normal subjects preferred tights in the rightmost position by a factor of 4 to 1, then confabulated about the reasons. None mentioned the position as a factor.¹²¹

Back to our right hemisphere-damaged patients. An inability to acknowledge parts of the embodied self, known as *asomatognosia* (Greek *a*, not, + *somat*-, body, + *gnosis*, knowledge) has been estimated to occur in 90% of all right hemisphere strokes, and in 100 cases examined by Feinberg, who has made the most extensive investigations of the phenomenon to date, it never once followed a left hemisphere stroke, always a right hemisphere one.¹²² It can be temporarily reversed by caloric vestibular stimulation of the right hemisphere (ie, irrigating the left ear with ice water).¹²³ You might be forgiven for thinking that only someone with actual and extensive brain damage could possibly deny a part of their own body, but the phenomenon can be replicated *simply by selectively inhibiting your right hemisphere*. In an experiment with 62 normal subjects that had their right hemisphere suppressed, 60 displayed either *anosognosia* (failure to acknowledge a deficit), or *asomatognosia* (failure to acknowledge a body part).¹²⁴ That’s all it takes to end up believing, with conviction, some very odd things about the world indeed.

The border between *asomatognosia* and *somatoparaphrenia* is somewhat artificial. There is a good deal of phenomenological overlap in many cases, and they tend to be caused by similar right hemisphere lesions, especially in either the right posterior parietal and insular area or right premotor cortex.¹²⁵

A case, resulting from a right posterior parietal stroke, is described by Hécaen & de Ajuriaguerra:

‘Give me your hand’: gives her right hand. ‘Give me the other one?’: withdraws her right hand from the examiner’s and places it in his other hand. If one repeats the request, she transfers her right hand from one hand to the other, making no effort to offer her left

hand. When she is confronted with her left hand, and asked whose hand it is, she replies: 'it's your right hand'.¹²⁶

One subject, reported by Bisiach and his colleagues Maria Rusconi and Giuseppe Vallar, was absolutely convinced that her paralysed left arm was her mother's.¹²⁷ She could not by any means be dissuaded from this position, and was dismissive when asked to explain what it was doing in her bed. However, amazingly enough, when her damaged right hemisphere was temporarily stimulated (again by caloric vestibular stimulation), her delusion was banished: she freely acknowledged the arm was hers, and seemed puzzled as to why she was being asked whose arm it was. Once the right hemisphere stimulation wore off, however, she was again quite adamant that the arm was her mother's. These findings have since been replicated.¹²⁸ Other patients have claimed that the offending arm was made of plastic, or that it was a dead hand someone had put in their bed. A white woman thought hers belonged to a little black boy in bed with her. Another was convinced that the nurses had carelessly bundled up his arm with the dirty laundry and sent it away to be washed.¹²⁹ (Remember, when it comes to the left hemisphere, it's always someone else's fault.) Ramachandran reports the case of a woman whose entire left side was paralysed, and was admitted to hospital because, as the patient put it, 'my daughter felt there was something wrong with me'.¹³⁰ The following conversation between Ramachandran and the patient took place:

Q: Mrs M, can you use your arms?

A: Yes.

Q: Can you use both hands?

A: Yes, of course.

Q: Can you use your right hand?

A: Yes.

Q: Can you use your left hand?

A: Yes.

Q: Are both hands equally strong?

A: Yes, they are equally strong.

Q: Mrs M, point to my student with your right hand.

A: [Patient points.]

Q: Mrs M, point to my student with your left hand.

A: [Patient remains silent.]

Q: Mrs M, why are you not pointing?

A: Because I didn't want to.

The next day, she answered similarly, but then pointed to her own left hand and asked Ramachandran, 'Whose hand is this?'

Q: Whose hand do you think it is?

A: Well, it certainly isn't yours!

Q: Then whose is it?

A: It isn't mine either.

Q: Whose hand do you think it is?

A: It's my son's hand, Doctor.

Todd Feinberg reports a series of such patients.¹³¹ ‘I told my brother to remind me to take this thing home with me or I’ll leave it here’, one says. ‘It’s a piece of useless equipment.’ Other possibilities suggested by his patients include that their left arm was a remote control, a telephone pole, ‘a stock option’, a perfume bottle, mother-in-law’s hand, a breast or a deodorant. A second patient who thought the hand was her mother’s also believed it was her mother who was in hospital and who had had the stroke, not she herself. Another repeated several times the same story that it was ‘a hand that was left on the subway and they brought it here and they put it on me’. (It’s ‘them’ again.) Another’s arm was his brother’s, which had been chopped off by gangsters and placed in a coffin. Another patient’s was still in the garbage, with a plastic cover: ‘You’ll find [it] there ... but be careful, though – the nails are very long, and very sharp!’

That there is an affective component – a dislike of the affected limb and *all that is associated with it* – is essential to the phenomenon. After a right hemisphere stroke, a woman exhibited a total unawareness of her severe left arm paralysis and repeatedly affirmed that the paralysed hand belonged to someone else. But, more intriguingly, while she was able to see and describe the rings she had worn for years and was currently wearing on her left (now disowned) hand, she resolutely denied they were hers. By contrast, she immediately recognised these rings as her own (and produced much veridical autobiographical information about them) when they were shifted to her right hand, or displayed in front of her. Equally she was prompt in acknowledging personal belongings that, in her previous experience, had not been ordinarily associated with the left hand (for example, a keyholder or a comb), even when she saw such objects in contact with that left hand. Thus her denial was conditional not on the situation alone (on her left hand), but on the existence of an emotional association with the left hand.¹³²

It is important to bear in mind that these are people whose other conversation shows no sign of delusion. They are not what we used to call ‘mad’. Yet according to Feinberg, ‘confabulations and delusions were repeated on more than one occasion, were reported with great conviction and were relatively refractory to correction by the examiner’.¹³³

In fact people with somatoparaphrenia – or actually any right hemisphere deficit delusional state, including schizophrenia – will scarcely

ever budge from their delusion in the face of any kind of evidence.¹³⁴ Here is a woman with a paralysed left arm:

Examiner: What is this over here? Take a look over here [indicating patient's left hand]. What is this?

Patient: Your fingers.

E: Take a good look. What is it? [Taps the back of patient's hand.]

P: The back of your hand.

E: The back of *my* hand?

P: Yes.

E: Suppose I told you that this was *your* hand?

P: I wouldn't believe you.

E: You wouldn't believe me?

P: No, no.

E: This is *your* hand.

P: No.¹³⁵

Sometimes the affected part is under alien control: once again it is not 'my' problem, it's what someone or something else is doing. A patient described by François Lhermitte showed no concern about being paralysed down his left side and was positively euphoric: 'it seemed as if the entire left-hand side of his body had disappeared from his consciousness and from his psychic life'. Three days later, however, this patient reported that from time to time an alien hand, which disturbed and annoyed him, came and placed itself on his chest. 'This hand presses on my tummy and chokes me'. 'This hand bothers me', he said again, 'it doesn't belong to me, and I'm

afraid it might thump me.’ He thought it might belong to the man in the next bed. Notice the emotional repertoire, from euphoria to paranoia by way of annoyance. Another patient came to believe that the left side of his body was ‘evil’ and controlled by external agents, perhaps by the devil in collusion with his dead father.¹³⁶ If that sounds a little like schizophrenia, don’t dismiss the thought: schizophrenia shares a very large number of characteristics with right hemisphere brain damage.

Some of Feinberg’s patients also exhibit yet another intriguing phenomenon which follows damage to the right hemisphere.¹³⁷ It is called ‘reduplicative paramnesia’. This is where the subject becomes convinced that there is a copy, or more than one copy, of some important aspect of the world: the self, a spouse, the environment. Two of his patients, quite independently, expressed the same belief that there were three or four hospitals with the identical name. The most elaborate case I am aware of involved a man who reported eight ‘impostor’ cities, duplicating the patient’s own: he said he had spent the last eight years wandering between them, without finding the real one. There were also eight duplicates of his wife and children, each duplicate living in a separate duplicate city with a double of the patient.¹³⁸ More recently a Hungarian patient described between 20 and 30 clones of himself, which he called ‘twinnies’ (the Hungarian neologism *ikri* reduplicates the already reduplicative ‘twins’, *ikrek*), but these were somewhat vague in nature.¹³⁹ In the latest review of the literature 45 cases were identified, of which 23 had unilateral lesions.¹⁴⁰ Twenty-two of these were right-sided, and the one left-sided case was a left-hander.¹⁴¹ Other reports to date invariably implicate the right hemisphere.¹⁴²

What seems to have happened is that the experienced world has fragmented. Instead of there being one person or place, consistent and persistent over time, there are a whole lot of different ones that come and go from existence, like ‘freeze frames’ or snapshots. Reading and registering the *uniqueness* of faces, and of real-world complex scenes, another right hemisphere faculty, has been lost. And so a very odd confabulation has been created to make sense of a world in which there is neither uniqueness nor continuity. Every change means a new start with a fresh copy, not a different aspect of the same unique, enduring whole in time and space.

There is a closely related phenomenon called ‘delusional misidentification’, seen in psychiatric patients, that also commonly involves dysfunction of the right temporoparietal region (with or without involvement of the left hemisphere). John Cutting refers to an ‘overwhelming link with right hemisphere damage’.¹⁴³ Patients with this disorder may develop the belief that someone they know is duplicated in different places at different times, and may mistake strangers for someone familiar. A patient of mine accused her husband of two-timing because she believed she saw him on several occasions with different women while she was out in the town shopping, at times when she knew he should have been at work. This curious condition is called Fregoli syndrome, after an Italian quick-change artist of the early 1900s. And right hemisphere deficit syndromes can result in something which looks like the opposite, but is really a different manifestation of the same phenomenon: the belief that a person you know very well is actually being ‘impersonated’ by an impostor, a condition known, after its first describer, as Capgras syndrome.

Delusional misidentification is sometimes thought to be associated with something called prosopagnosia, the inability to recognise faces, which is also generally a right hemisphere deficit syndrome. But this cannot be the whole story, not only because it has been identified in blind subjects,¹⁴⁴ but because it can involve inanimate objects, as well as people. Another patient of mine, for example, began a vendetta against someone who, she believed, had entered her bedroom and subtly changed all her clothes for copies of a slightly inferior quality, something she could tell merely by touching them. Once again the uniqueness and persistence of a whole has fragmented. If something is experienced slightly differently on a different occasion, it must be a different entity – because things *do not change*. This is what makes Fregoli and Capgras syndromes, which look like the opposite of one another, actually the same in terms of ontology. If you had long hair and a smile when I left you in the morning, and you have short hair and a frown when I come back in the evening, I don’t normally assume you are being cleverly impersonated by someone else, or that you are a quick-change artist. I assume you are getting used to a bad haircut. As a way of joining up the dots, it is a tad more credible. But, once again, joining up the dots to see the whole is a quintessential function of the right hemisphere, not the left. Some such right hemisphere deficit, resulting in fragmentation of the sense

of self, may be involved in dissociative states and multiple personality syndromes.^{[145](#)}

ATTENTION AND DEVITALISATION

The story of devitalisation begins with cutting things up. This brings us again to the relation between the whole and the parts. The left hemisphere begins with parts, and any idea of the whole is built up from those parts. By contrast, the right hemisphere begins with the whole and any ‘parts’ are just aspects of the whole that have been artificially decontextualised. This follows directly from their different modes of attending.

Although you may imagine that you construct the world by putting together the bits that your gaze lands on, adding the pieces one by one and recognising that this must be – tada! – your living room, in fact it is the other way round: you take in the whole first, and then your gaze is attracted by particular parts. The exploration of complex scenes begins with a global take, characterised by short visual fixations and long-range saccades (brief, rapid eye movements), which within a few seconds proceeds to a focal mode of processing.¹⁴⁶ This correlates with a shift of activity from the right to the left hemisphere.¹⁴⁷ When you see a figure of the number 4 composed of lots of little circles, or an H composed of lots of little 2s (see Fig. 7), you normally see the 4 and the H first, and the details, the little circles and 2s, come only later. This phenomenon demonstrates what is known as the ‘hierarchy of attention’, which means that we see things whole with the right hemisphere first, before homing in on details with the sharply, but narrowly, focussed gaze of the left hemisphere. As one might expect, this hierarchy is reversed in schizophrenia, where the right hemisphere-based overview is supplanted by the left hemisphere’s detail-focussed view.

The right hemisphere gets the form, the shape, the whole: the left hemisphere gets the bits and pieces.

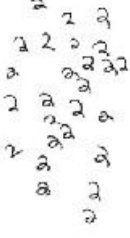

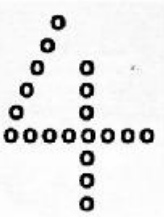

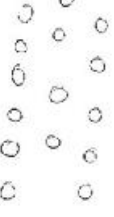

Target stimulus	LH intact	RH intact
		
		

Fig. 7. Drawings of targets from memory, in right hemisphere-damaged (centre) and left hemisphere-damaged (right) patients (examples from author's clinical material)

When the right hemisphere is damaged, things fall apart. For example, if asked to draw a person, subjects with damage to the right posterior hemisphere can't put the bits together, but, in repeated attempts, put the limbs in the most extraordinary places.

Fig. 8. Assembling a mannequin from parts: (A) correct configuration; (B) attempt by patient with right posterior tumour (from McFie, Piercy & Zangwill 1950)

Whereas subjects with autotopagnosia (see below), following left hemisphere damage, retain the overall form, but not the pieces, right hemisphere-damaged subjects retain the pieces, but not the overall form. One patient, asked to draw an elephant, can draw the parts separately – a trunk, a tail, an ear – but can't put them together to form a recognisable animal. He is no better able if given a model of an elephant to assemble. In general, the overall shape is lost and attention is focussed on one or two features which are thought to identify the item.¹⁴⁸

This loss of the whole at the expense of the parts is reflected in the fact that the hemispheres 'see' the body, too, in different ways. One difference is that the left hemisphere sees the body as an object 'out there' in space alongside other objects, while the right hemisphere feels the body to be what we experience as a whole 'from the inside'. What is conventionally called the body image, but which I will henceforth call the body schema, is in the right hemisphere. I change the terminology because this is not, as in common parlance, just a visual image, but a multimodal image of the body, as experienced, and taken as a whole.

Devitalisation is also sometimes dramatic. With the right hemisphere no longer available to bring the left side of the body into awareness, the left hemisphere may substitute only a structure of mechanical parts down that side. One patient described by the Austrian neurologist Hans Ehrenwald reported that, following a right hemisphere stroke,

where the left half of his chest, abdomen and stomach should be, a plank has been inserted. It goes right down to his anus, is divided into compartments by crossbeams, and has a hole in its undersurface. Food doesn't pass in the usual fashion through the stomach and intestines, but is pumped into the compartments of the shelving and passes out by the hole at the bottom. All that applies only to the left half; on the right side, all the organs are in order. He runs his hand gloomily over the left side of his chest, and points: 'Here is the plank: there's no mistaking it. You can feel it clearly under your hand.'¹⁴⁹

That alerts us to another thing we notice in the accounts of their bodies by patients with right hemisphere disorders: how often the offending body

part is mistaken for an *inanimate object*, either dead or never alive. This is not just a way of saying it is not functioning. People with left hemisphere strokes almost always recognise the paralysed arm as part of the self and want to rehabilitate it. People with right hemisphere strokes sometimes see it as another person altogether, and give it a nickname – Floppy, Dopey, Johnny – but more often see it as not alive – or *never-alive*.¹⁵⁰ Thus a patient may declare ‘I don’t know what the hell it is!’, before deciding it is ‘dead wood’.¹⁵¹

Ehrenwald published accounts of several left-hemiplegic patients (therefore with right hemisphere lesions). One patient’s left hand was ‘as long, as dead and as lifeless as a snake’; another found that his left extremity was ‘alien, dead ... utterly lost to him’.¹⁵² A third

complained of feeling that his body was becoming more and more divided into parts, that he was losing it bit by bit ... ‘Where can my body have gone? All there is here is debris that I don’t recognise.’¹⁵³

And for yet another:

even the internal organs of the left half of the body appear altered, in fact are completely non-functioning; and are replaced, as he puts it in delusional fashion, by a lifeless mechanism, alien to the body – part of the external world.¹⁵⁴

The emotional alienation involved here is either directed at a body part, or at the whole body. But sometimes, after right hemisphere stroke, as part of the general hollowing out of emotion, there can be an alienation from the self as a whole, from the subjective stance that guarantees personhood. Thus Ehrenwald describes a young woman who, following a right hemisphere stroke, started to speak of herself only in the third person.¹⁵⁵ This is a not uncommon finding in autism; and occurs by implication in schizophrenia, where third-person auditory hallucinations, in which voices do not speak *to* the subject, but *about* him or her, are considered a ‘first rank’ symptom.¹⁵⁶ It appears to signify a loss of the unreflective,

spontaneous grounding of the self in the world, without which nothing any longer seems real.

There is an intuitive connexion between cutting things up into parts and their being no longer alive, which is borne out by brain functioning: a failure of global processing, as in right hemisphere damage, impairs recognition of living things, while a failure of local processing, as in left hemisphere damage, impairs recognition of non-living ones.¹⁵⁷ And there is a particular affinity of the left hemisphere for both inanimacy and analysis into parts. It is the left hemisphere alone that codes for non-living things, while both hemispheres code for living things – though the right hemisphere has an advantage for the living;¹⁵⁸ at least one study has found a clean divide between the hemispheres, the left coding for the non-living, and the right for the living, regardless of the task.¹⁵⁹ Another found that responses selective for animacy arose only in the right hemisphere, and that animals and non-animals formed ‘distinguishable clusters in the population code of the right, but not left, amygdala’;¹⁶⁰ yet another that animals’ names and appearances activated preferentially the right hemisphere, especially the temporal region, and conversely that names and appearances of inanimate objects and, especially, tools, preferentially activated the left hemisphere, especially the left temporal region.¹⁶¹ A subject with schizophrenia, which mimics right hemisphere deficits, reported ‘I had a sort of fascination about waxworks, surreal imagery.’¹⁶² And body parts – like ‘cut up’ bodies – sort with *inanimate things*.

Moreover, there is such an affinity between the left hemisphere and tools, and actions of grasping, that just referring to tools or grasping activates the left hemisphere, *even in left-handers*, despite the fact that left-handers habitually use the right hemisphere (left hand) to grasp objects and use tools and instruments in daily life.¹⁶³

Instruments are the natural province of a hemisphere whose concern is manipulation of the environment, whose concern is ‘instrumental’. Of all things, machines can best be understood partwise: they were made by us, we put them together from parts, and we know therefore the purpose for which they were designed. Living things, however much we may have got used to thinking of them in this way, are not machines: we didn’t make them, they were never just ‘put together’ and they don’t have an instrumental purpose. And as a further demonstration that the distinction

involves manipulation, ‘instruments’ of the musical variety, which are not actually ‘instrumental’ in the philosophical sense, have repeatedly been found to sort in the brain, not with inanimate objects and tools, but in the right hemisphere with living things.¹⁶⁴ The musician ‘does not only manipulate the instrument like a separate object, but lives in it like a limb and inhabits the expressive musical space it opens’.¹⁶⁵ Impaired recognition of musical instruments – whether by sound, sight or concept – is associated with damage to the right superior temporal gyrus.¹⁶⁶

By way of illustration, Amy Belfi and colleagues presented a contrasting pair of cases. A subject with left frontotemporal damage was almost perfect (94%) at recognising musical instruments but poor (33%), as one might expect, at naming them. A subject, however, with right parietotemporal damage was 100% correct at naming, but only 44% correct at recognising; she incidentally demonstrated what is called superordinate categorisation, typical of the left hemisphere – eg, saying ‘musical instrument’ for ‘flute’.¹⁶⁷ the loss of fine discrimination.

In the absence of the left hemisphere, things come alive. In a study in which subjects had one or other hemisphere suppressed, those with their left hemisphere suppressed were ‘like young children or representatives of archaic societies’, in that they attributed life to a watch ‘because it goes’, or the moon because it moves across the sky, or to a stone ‘because electrons rotate within it’.¹⁶⁸ They were natural animists. Animacy comes from appreciation of a human context, something at which the right hemisphere is superior to the left. In his work with the Ojibwa, an indigenous people of North America, anthropologist Pete Hallowell discovered that many words for inanimate objects are within the animate noun category.¹⁶⁹ He explained that not *all* stones are considered ‘alive’ within Ojibwa society. but that their aliveness emerges through involvement with others; they are alive ‘through their position within a relational field’.¹⁷⁰ This immediately suggests right hemisphere ontology.

The corollary, that right hemisphere suppression causes the living to appear inanimate, is demonstrated by the account of patients with right – particularly right parietal – damage. One such woman, who was not depressed, reported that

sometimes I do not seem to know who I am, I doubt my own existence, I feel like a piece of furniture. I do not feel either a human being or an animal. I can feel the heat and the cold, but at the same time it feels very weird. I walk, but I just cannot convince myself that I am walking, as I have this feeling as if I could not move, as if I was a piece of furniture.^{[171](#)}

In the two above examples, the association of animacy with motion, and of inanimacy with stasis, is made explicit: the link is both intuitive and present at the level of hemisphere difference.

Finally, I mentioned that it is easier for the right hemisphere to adopt the attentional role of the left, if required, than for the left hemisphere to adopt the role of the right. This asymmetry is by no means limited to attention. After severe infantile damage to the left hemisphere, language can develop in the right hemisphere; but the left hemisphere is more rarely able to take over after damage to the right.^{[172](#)} There is active inhibition of right hemisphere language by the left hemisphere, which comes to light when the left hemisphere is suppressed; if the inhibitory effect of the left hemisphere is attenuated or suppressed, the right hemisphere proves to have a considerable vocabulary, including long, unusual and non-imageable words.^{[173](#)} The reverse phenomenon, that, eg, facial processing, a typical right hemisphere function, is released in the left hemisphere when the right hemisphere is temporarily inactivated ‘remains inconclusive’.^{[174](#)} If the left parietal lobe is ‘knocked out’, the right parietal can do its job, but not the other way round.^{[175](#)}

According to one research group, findings

suggest that the right hemisphere contributes to the development of left hemispheric function. Moreover, the right hemisphere and its functions ... develop earlier than those assigned to the left hemisphere, as confirmed by a recent functional imagery study.^{[176](#)} Putting all the findings together, the right hemisphere seems to have a “nurturing” function for the development of the left hemisphere ...
^{[177](#)}

The Master appoints and nurtures his emissary.

The right hemisphere is dominant in human infants,¹⁷⁸ and in the first years of life.¹⁷⁹ In a study of cause and effect connectivity between cortical structures, researchers found that first, overall, and in opposition to the clichéd presumption, there was not only a dominance of top-down over bottom-up causation, but of the right hemisphere over the left.¹⁸⁰ And second, they found that the right ventrolateral prefrontal cortex had more impact on the function of the rest of the brain than any other single area in the brain, with effects especially on the right frontal pole generally, and the left ventrolateral prefrontal cortex, as well as on both right and left amygdalae and hippocampi. As far as top-down causation was concerned, the only exception was an excitatory influence of the right hippocampal formation on the right frontal pole and right amygdala. Another study found an excitatory influence of the right amygdala on ‘higher’ centres in both sides of the brain.¹⁸¹ It looks like the right hemisphere, particularly the right frontal pole, but also, interestingly, the ‘lower’ areas, such as the right amygdala and hippocampus, are critical to our maintaining a sense of reality.

This merely adds to the evidence that I discussed in *The Master and his Emissary* at considerable length that the right hemisphere is primary in the bringing about of the experienced world.

SUMMARY

Attention does not just change things in some rather nebulous way. Attention is responsible not just for the *how* (though it is), not just for the *what* (though it is), but, as far as the left hemisphere is concerned, for the *whether-at-all* of existence. What it doesn't attend to, as far as the left hemisphere is concerned, doesn't exist.

Left hemisphere attention is sharply restricted in space and time, which is, after all, the four-dimensional world in which we live. It tends towards precision, but at the expense of depth. It is no longer true to the expansive, always moving, always changing, endlessly interconnected nature of reality. One way of putting it is that the left hemisphere can provide some sorts of knowledge *about* the world, as it would be scrutinised from a certain theoretical point of view effectively outside the realms of space and time (as on a map); whereas the right hemisphere provides us with the knowledge *of* the world in space and time (as experienced). Constraining attention, left hemisphere fashion, makes coherent wholes dissolve, and brings things to a standstill: reality leaches out.

The left hemisphere's limited appreciation of depth in space and time is in keeping with its tendency towards stasis. It seems to lack appreciation, not just of motion, but of emotion; it relatively lacks appropriate emotional depth, or concern, tending to be irritable or facetious, especially when challenged. It tends to disown problems, and pass the responsibility to others; is overconfident about what it cannot in the nature of things know much about; fabricates (often improbable) stories to cover its ignorance; sees parts at the expense of wholes; tends to see 'from the outside', rather than experience 'from the inside'; and has an affinity for the inanimate, and for tools and machines in particular.

It is also quite confident it is right.

PERCEPTION

Thinking is more interesting than knowing, but not than looking.

—*Johann Wolfgang von Goethe*¹

To repeat: don't think, but look!

—*Ludwig Wittgenstein*²

PERCEPTION IS NOT THE SAME AS ATTENTION, AND NOT AT ALL THE SAME AS thinking. But the world we choose to attend to, indeed choose whether and how to attend to, is nothing without perception. 'We live in two worlds, the world of sight and the world of thought', wrote Friedrich Max Müller, one of the most celebrated philologists of the nineteenth century, 'and, strange as it may sound, nothing that we think, nothing that we name, nothing that we find in our dictionary, can ever be seen or heard, or perceived.'³ Perception is the act whereby we reach out from our cage of mental constructs to taste, smell, touch, hear and see the living world.

Let's begin by turning to perception in the most basic possible sense: the capacity of each of the senses to make discriminations, and thus help us to bring about a world of experience at all. How veridical is the perception of either hemisphere? Which should we be more prepared to trust?

At first, the brain's capacity for divided attention was almost wholly in the service of perception – in *either hemisphere*. It was devoted to delivering sensory information about the world, through eyes and ears and

touch, and through the sense of smell. And this need for immediate sensory information of the highest quality in both hemispheres goes on a very long way up the evolutionary tree, almost as far as human beings. Almost – but not quite. Because in us something new happens: to be precise, it starts happening in the great apes. It is the ability to use symbols – tokens or representations for things. And in humans it is advanced out of all recognition by language, which gives us a virtually inexhaustible way of mapping the world, to which perception is, to all intents and purposes, irrelevant – and from which it may even prove a distraction. Sensory perception goes on, of course, in each hemisphere, but it becomes of comparatively less importance for the cortical left hemisphere, now devoted to re-presentation.

HEMISPHERIC DIFFERENCES IN NORMAL PERCEPTION

Perception is not naïve: we do not cobble together independent stimuli – white fur, long ears, whiskers – to form a rabbit. We see the hat, and we expect a rabbit even before it appears. When we see what are conventionally thought of as different ‘percepts’, we are already going to meet them with an image of our own – we see them as part of a whole that comes into being at once together. Here again the right hemisphere has the advantage since its capacity to see the whole is reflected in greater interregional connectivity in the right hemisphere, whereas the left hemisphere is better at processing ‘simple, unimodal stimuli’.⁴ Tasks that involve integration across sensory modalities are significantly harder for patients with right hemisphere than left hemisphere damage, whatever the modalities in question.⁵

To be good at perceiving is to be good at *integrating* information. It is bound up with widespread brain function, particularly with preparing to act or simulating action – not just, or even mainly, as a *consequence* of perception, but as a *basis* for perception. For example, monkeys with bilaterally intact visual (striate, prestriate and temporal visual) cortices became nonetheless functionally blind after the removal of areas of *non-visual* cortex which respond to sight.⁶ Or speech: obviously, listening to speech affects the power of speech, but does the power of speech have an effect on the capacity to hear speech? It seems so.⁷ Disrupting premotor cortex disrupts the perception and understanding of action language, as well as its execution.⁸

Merleau-Ponty saw perception as a reciprocal encounter. It is a position I strongly defended in *The Master and his Emissary*. Experience is a sensorimotor – and intuitive – participation, a fusion of one’s own awareness with awareness in the world. Speaking of his perception of the blue of the sky, Merleau-Ponty wrote that ‘I abandon myself to it and plunge into this mystery, it “thinks itself within me”...’⁹ Perception is not passive reception, but participation. (As is all consciousness, but that is a story for later.)

The insight that the right hemisphere is better at perception has a long history. As long ago as 1864, only three years after Broca’s first papers

describing the case of ‘Tan’, a subject with a left frontal lesion accompanied by aphasia,¹⁰ and thus signalling the beginning of the modern understanding that the brain hemispheres were different in nature, John Hughlings Jackson, the father of British neurology, wrote: ‘If, then, it should be proved by wider evidence that the faculty of expression resides in one hemisphere, there is no absurdity in raising the question as to whether perception – its corresponding opposite – may not be seated in the other.’¹¹ He was referring to speech expression and speech perception, but 10 years later he added visual perception: ‘the posterior lobe – or let us speak more generally – the hinder part of the brain on the right side, is the chief seat of the revival of images in the *recognition* of objects, places, persons, &c.’¹² And, astonishingly, in the earliest known speculation on the nature of hemisphere difference, Greek physicians in the third century BC already held that the right hemisphere was specialised for perception.¹³ This was in an era when there were very few brain scanners. Recent research strongly bears out their insight.

Visual perception

The right hemisphere has in fact been shown to be better at a whole range of pre-cognitive aspects of vision. It is superior at stimulus detection and localisation, as well as depth detection; it is more accurate at size estimation, and better at orientation matching, adapting to orientation, and detecting small differences in line orientation.¹⁴ It is also better, which may come as a surprise, at visual (hyper)acuity: it performs better at Vernier tasks (requiring the ability to discern a slight misalignment between two line segments or gratings).¹⁵ As we have seen, unlike the left hemisphere, which knows how to categorise a spatial point (above, below, to the right, to the left, of something else), the right hemisphere knows where it actually is – its spatial co-ordinates, if you like.¹⁶ It is better at pattern recognition.¹⁷ In addition, patients with right hemisphere damage are far more likely than their left hemisphere-damaged counterparts to have difficulty separating figure from ground, or real contours from shadows;¹⁸ and in contour detection,¹⁹ as well as recognising objects from unusual angles, or from incomplete information.²⁰ The right hemisphere is far superior in mental

rotation – which involves thinking in three dimensions, not two.²¹ ‘The right hemisphere’, writes Gazzaniga,

is easily able to do tasks that involve discriminations that are spatial in nature, such as detecting whether two images are identical or mirror-reversed, detecting small differences in line orientation, and mental rotation of objects, while the left hemisphere is dismal at these assignments ... It also turns out that the right hemisphere is exceptional at perceptual grouping. For example: if you show partially drawn figures to the right hemisphere, it can easily guess what they are, but the left hemisphere can’t guess until the figure is nearly completely drawn.²²

It has been suggested that the right hemisphere’s ability to see the whole somehow depends on its (undoubted) ability to deal better with incomplete information. But it seems likely that the effect works the other way round: it can deal with incomplete information, because it sees the whole. For example, in a study in which the right hemisphere was shown to be superior at contour detection, ‘contour and non-contour stimuli had the same spatial frequency spectra ... the results challenge the view that the right hemisphere advantage in global processing depends on a specialization for processing low spatial frequencies’. A term such as ‘spatial frequency’ can easily be off-putting, but in everyday parlance it means how much information is present. Low spatial frequency means not much information is present, so you have to do extra work to make out what you are looking at. And according to a critical survey of the area in the same paper, ‘the right hemisphere’s predominance in spatial-frequency analysis is, apparently, only a manifestation of its special competence in various perceptual functions’.²³ The point being made by the authors of the paper is that this is just one more way of demonstrating that the right hemisphere is better at *reading* the stimulus, across various perceptual modalities, since, when the signal is easy to read, the left hemisphere is slightly quicker at detection (it tends, compared to the right, to jump to conclusions), but when the signal is any way degraded, partial or hard to read, the right hemisphere is more accurate.

Even this partial left hemisphere advantage is true only for brief exposures, since with longer exposure, there is ‘a trend to a right hemisphere advantage irrespective of the [spatial frequency] content’.²⁴ In other words, if you want an accurate assessment rather than a quick one, the right hemisphere is to be preferred. In fact there is evidence that the left hemisphere gets less reliable as you give it more time to respond – perhaps because it is then prone to rely on conscious processing, which immediately limits possibilities.²⁵ Nonetheless, interpretation of ‘low spatial frequency’, giving the intuited whole, comes first, courtesy of the right hemisphere, and ‘high spatial frequency’, focus on detail, comes later, courtesy of the left.²⁶

And here I’d make a general reflection on the psychological literature on hemisphere difference to date. The left hemisphere has got a long way on its reputation as the bright one precisely because of its speed. In the lab, ‘superiority’ at a task very often means being able to do it *quicker*. But right across the board there is a pretty significant rider to this. The left hemisphere is faster, where it *is* faster, as long as the stimulus is clear, and familiar, and a stock response is required. What has been demonstrated time and again is that if there is any ambiguity or uncertainty about the stimulus, or it is unfamiliar, or the stock response is not what is required, it is the right hemisphere that is more accurate. The right hemisphere’s devil’s advocate tendencies – ‘is there another way of seeing this?’ – lose it the lead by milliseconds when the response needs to be quick and dirty. But they win out everywhere else, where a more thoughtful response is required, because the right hemisphere is more in touch, more nuanced in weighing up what is going on, and more insightful across the board.

Incidentally, some doubt has been cast on the validity of tests carried out using cathode ray tube displays (which until recently much of the research corpus has been), because they deliver a greater luminance in the right visual field, the province of the left hemisphere. Since greater luminance carries an advantage in reaction time, and typical interhemispheric differences in reaction times are small, this is potentially significant; and one study claims to have ‘shown that previous reports of right visual-field [left hemisphere] advantages for vocal responses are an artefact of the luminance asymmetry of computer screens’.²⁷ According to Nowicka and Tacikowski’s review of the area, ‘unfortunately this report has been largely overlooked by the neuroscience community, despite the fact

that luminance asymmetry could have substantial implications for the interpretation of the findings of many studies'.²⁸

All in all, the left hemisphere is less reliable in perceptual interpretation of experience, which goes with its being more likely to jump to conclusions, getting it right when the stimulus is predictable, but wrong when it is not; the right hemisphere is more cautious, and more reliable in the long run. Of which more presently.

The human brain can make very fine discriminations of colour. Those with normal colour vision experience a vastly rich colour spectrum, with estimates of, conventionally, 2–3 million discernibly different colours that may be seen together in an 'almost infinite' number of possible combinations.²⁹ Indeed, according to one recent study, 'a more realistic if conservative number of distinguishable object colour stimuli' is about 40 million.³⁰ Amongst the many pre-cognitive aspects of vision at which the right hemisphere excels is colour perception and brightness sensitivity.³¹ The perception (as opposed to naming) of colour in mental imagery under normal circumstances activates only the right fusiform area, not the left;³² and imaging studies, lesion studies and neuropsychological testing all suggest that the right hemisphere is more attuned to colour discrimination and perception.³³

A further difference is the way the two hemispheres deal with imagery. Since the left hemisphere is less in touch at the perceptual level, its world is more abstract or conceptual – generalised and theoretical.³⁴ Its views are hardly *views* at all, but 'abstract, view-independent representations', presumably derived from real-life views taken by the right hemisphere: according to Patrik Vuilleumier and colleagues,

left fusiform neurons might code for view-independent conjunctions of characteristic features, whereas right fusiform [neurons] might represent complex features in a view-specific (but scale-invariant) holistic manner.³⁵

In Aristotle's view, ideal exempla are simply derived from real-life instances, shorn of individual features and context. On this view, the left hemisphere 're-presents' a digest of the specific views presented by the right, with all their complex features and holistic roundness neatly excised.

However, references to specific points in real space are, as Stephen Kosslyn points out, more useful for getting around in the world than theoretical generalisations: ‘one needs to know about the specific case, not its general category’. According to him, it is the right hemisphere that primarily produces ‘vivid, in-context, external’ images, while the left hemisphere primarily deals in ‘non-vivid, out-of-context, internal’ images.³⁶ One revealing detail: while there is no left hemisphere advantage for recognising objects in general – rather the opposite – there is such an advantage for recognising *tools*.³⁷

Auditory perception

The greater part of our perception of the world comes by sight. What about the other senses? The human ear can discriminate, it is said, 340,000 tones.³⁸ Pitch discrimination, as well as some other aspects of tone processing, has repeatedly been found to be superior in the right auditory cortex,³⁹ by contrast with the processing of meaningless noises, such as clicks, in which there is a left auditory cortical advantage, a difference thought to relate to its specialisation for language.⁴⁰ The right posterior superior temporal area has in particular been noted to play a key part in a range of auditory processes, including the inflection of speech,⁴¹ the timbre of the voice,⁴² and phrasing.⁴³ In both music and speech, melody, tone and pitch-processing,⁴⁴ as well as harmony in music,⁴⁵ are almost always mediated via the right hemisphere. Rhythm and metre in speech, and complex musical rhythm, are also right hemisphere mediated.⁴⁶ However, basic metrical rhythms are mediated by the left hemisphere, particularly by Broca’s area.⁴⁷

All of this is true of non-professional musicians only. Professional musicians have a more bilateral representation of music (see *The Master and his Emissary* for discussion of possible reasons).⁴⁸

Auditory rhyme probably requires both hemispheres:⁴⁹ one of the effects of callosal agenesis – congenital absence of the entire corpus callosum – is the loss of appreciation of rhyme.⁵⁰ It seems that a connexion between left and right inferior frontal gyri is necessary.⁵¹ However, the right posterior superior temporal gyrus may again play the key part.⁵²

In addition, the right hemisphere specialises in ‘higher-order processing’, integrating the whole of auditory space, and enabling absolute (as opposed to relative) localisation of a sound – ie, just as with vision, knowing where the perceived stimulus actually is.⁵³ Lesions to the left parietal lobe have some effect on the localisation of sounds coming from the right, but right parietal damage disrupts the spatial processing of *all* sounds, whether from left or right – a finding which is in keeping with what we know of the hemispheres’ different attentional fields.⁵⁴

Olfactory and gustatory perception

The acuity of eye and ear is, however, as nothing to that of the nose. An estimate of a lower limit of 1,720,000,000,000 (otherwise known as 1.72 trillion), for the number of olfactory stimuli that humans can discriminate is apparently, I was abashed to learn, conservative.⁵⁵ The characteristic scent of a rose, for example, is produced by a blend of not, perhaps, five, or 15, but 275 components, none of which on its own smells like a rose.⁵⁶ A considerable body of evidence suggests that olfactory recognition and discrimination are preferentially carried out in the right hemisphere, ⁵⁷ especially the right orbitofrontal cortex, though, oddly enough, emotional reactions to scent may be stronger in the left hemisphere, possibly a relic of its role as predator.⁵⁸

Apart from five very basic tastes – salt, sweet, sour, bitter and umami – which come from the tongue, all flavours come from the olfactory sense. In a test of wine recognition, control subjects showed activations predominantly in the right hemisphere. Wine experts, however, used both hemispheres, and at times relied more heavily on the left hemisphere. The investigators put this down to the fact that they ‘work simultaneously on sensory quality assessment and on label recognition of wine’.⁵⁹ Or at any rate, naming.

Tactile perception

The sense of touch is superior in the left hand (right hemisphere);⁶⁰ the right hemisphere is generally more sensitive to tactile stimuli, ⁶¹ and

complex tactile stimuli are better read by the right hemisphere than the left.⁶² Feelings of warmth, and temperature discriminations in general, are associated with right hemisphere activation.⁶³ Visual discrimination of texture depends on the right posterior parietal cortex in humans (as it does in rats), although one report suggests the left parietal region may also play a role.⁶⁴ The ability to perceive the workings of the body internally, known as interoception – for example, awareness of one’s own heart beat – is right hemisphere (specifically, right insula) mediated.⁶⁵

And remember, even perceptual links between *words* are also made primarily by the right hemisphere.⁶⁶

So much for primary sensory perception.

Local vs global perception

One important element in perception is the ability to make sense of a stimulus using contextual information. This requires a swift capacity to synthesise bottom-up, local, information, with top-down, holistic, information, a process that depends principally on the right hemisphere. Patients with brain lesions who show perceptual organisation deficits commonly have damage to the right temporal lobe or right temporoparietal junction,⁶⁷ and less commonly to the right frontal lobe.⁶⁸ While the left hemisphere underwrites local attention, the right hemisphere underwrites global attention, as we saw in the previous chapter – *and* the ability to switch between them.⁶⁹

This last ability is easy to pass over. But it’s not just another technical difference between the hemispheres. It inevitably makes a difference to the world we *perceive*. What it means is that *both* to perceive the form of something as a whole, *and* to see it differently from the way you are accustomed to see it, depends on the way of taking in the world that is underwritten by the right hemisphere of the brain. If you think and adopt the way of being of the left hemisphere world, not only will you struggle to see the overall shape, but you won’t be able so easily to switch – or even be aware that you can. If someone else tells you they see something quite different there, you might well, sincerely but wrongly, believe that they must be mistaken.

Fig. 9. Bi-stable image of stairs (from Schröder 1858)

There is something known as perceptual rivalry, which is the antagonism between conflicting interpretations of a bi-stable image (an image that has two possible stable configurations) such as Schröder's stairs (Fig. 9) – are we looking at the stairs from above and to the right, or from below and to the left? Normally we can flip between percepts more or less at will. One special case of perceptual rivalry is binocular rivalry, where it is not that the same image is seen by both eyes (while allowing more than one interpretation), but that the images given to each eye are different – and not strictly compatible.

Bi-stable percepts engage primarily right hemisphere (frontoparietal) networks, but also to a lesser extent left hemisphere regions, which is what one would expect, on the basis of interactive competition between the left hemisphere's need to achieve a single stable result, and the right hemisphere's attempt to free things up and see other possible alternatives. What is critical, though, for both to be of use, is the part played in this process by being able to switch, or 'unstick', perception. EEG evaluation (electroencephalography, a measure of regional brain activity using leads, taped to the scalp, to monitor the brain's electrical activity) is superior to functional neuroimaging whenever one is looking at something in which split-second timing is crucial: EEG measurement shows that the right inferior parietal cortex is the key area that activates just prior to a perceptual reversal.⁷⁰ fMRI, or functional magnetic resonance imaging, gives detailed evaluation of which areas are active, but does so over 'time slices' that are usually several seconds thick, where EEG gives an instantaneous record. Having said that, in this case a virtually identical result was in fact achieved using fMRI, also implicating the right inferior parietal cortex.⁷¹

A large majority of other studies have reported, in the words of one research group, that ‘activity specific to the rivalry condition was strongly lateralized to the right hemisphere’, implicating more specifically right inferior and superior parietal regions, and right inferior frontal cortex, including the insula, as of critical importance to switching.⁷² In addition, lesion studies show that right hemisphere-damaged, but not left hemisphere-damaged, individuals have problems with binocular rivalry.⁷³ Moreover, temporarily suppressing the posterior right parietal cortex using transcranial magnetic stimulation (TMS) in normal subjects disrupts its capacity to facilitate perceptual shifts.⁷⁴ (TMS is a non-invasive procedure, which employs a hand-held magnetic coil to stimulate or suppress, depending on the frequency of pulses delivered, the activity of the underlying cortical area.)

Thus the right hemisphere makes it possible to switch interpretations, whether between interpretations of what both eyes see, as in the stairs (perceptual rivalry), or between what each eye sees (binocular rivalry); and right hemisphere damage makes it hard to switch, in line with what I call the stickiness of the left hemisphere.

The ability to see the whole, to make sense of percepts in terms of knowledge about the real world, to see how to group things together to make sense, to see global forms and complex images, improves with age and experience, reaching normal adult levels only by late childhood at the earliest, and for some aspects not till adulthood itself: experiments with complex visual displays show that in normal adolescents perception is biased toward representing local elements rather than perceiving the whole.⁷⁵

THE HEMISPHERES AND PATHOLOGIES OF PERCEPTION

So much for the normal functioning of the brain in perception. What does abnormal functioning tell us?

Patients with brain lesions who show deficits of perceptual organisation generally have damage to the right temporal lobe or right temporoparietal junction,⁷⁶ less commonly to the right frontal lobe.⁷⁷ Some patients with Alzheimer's disease exhibit deficits in perceptual organisation, and such patients usually have greater right hemisphere involvement in the disease.⁷⁸

Not to see the whole is to see things out of context. For this we depend on the right hemisphere, which has the capacity to integrate extraordinary amounts of information over many areas. This capacity is embodied in the physical structure of the right hemisphere, whose anatomy and neuronal structure are more suited to holistic, 'summative' processing than that of the left hemisphere.⁷⁹ There appears, even, to be a right hemisphere advantage for holistic *word* processing, despite the clear left hemisphere advantage in language comprehension overall.⁸⁰

Although I have referred to them separately, respect for context implies respect for embodiment – itself an important 'context' – respect for what is concrete and unique, being embedded in the world; similarly abstraction and generalisation inevitably move in the opposite direction, towards decontextualisation and remoteness from the embodied world in which we live. What about perception and the body?

It is widely accepted in clinical neurology that the right hemisphere is specialised for perception of the body.⁸¹ I have mentioned that the right hemisphere is more in touch with the body in the sense of having more profuse connexions with the limbic system, the ancient part of the brain that mediates emotion to 'higher' cognitive centres, and vice versa.⁸² Moreover the right frontal pole has a key role in regulating the hypothalamic-pituitary-adrenal axis, which is the neuroendocrine interface between the body and emotion, essential to our subjective appreciation of the body's physiological condition.⁸³ And pleasant or painful sensations of temperature, pain from muscles and abdominal organs, awareness of heart beat, sensual touch and sexual arousal all produce predominantly activation in the anterior insula of the *right* hemisphere.⁸⁴

‘Several lines of evidence suggest’, writes Orrin Devinsky, Professor of Neurology at New York University, in a review of the subject, ‘that the right cerebral hemisphere is dominant for the sense of physical and emotional self, specifically, for an individual’s awareness of his or her own corporeal being and its relation to the environment and affective state’.⁸⁵ That’s quite a chunk of reality. Specifically the right hippocampal formation is, according to Boris Velichkovsky, ‘unique in its holistic representation of surrounding space, which seems to function as the common interface for the bodily “self” as well as for higher-order thought and feelings.’⁸⁶

What about other aspects of the self?⁸⁷ The right hemisphere, especially the right inferior parietal lobe, is of vital importance for our awareness of self, beginning with the physical self, but going beyond that.⁸⁸ As I have suggested elsewhere, though clearly neither hemisphere can on its own constitute the self, the contributions to the ‘self’ from either hemisphere are distinctively different. At the risk of over-simplification, the objectified self, and the self as an expression of will, is generally more dependent on the left hemisphere; whereas the self as empathically inseparable from the world in which it stands in relation to others, and the continuous sense of self, enduring over time, are more dependent on the right hemisphere.⁸⁹ The verbally self-interrogating self, ‘judging what is occurring, trying to figure out what that trait word means to the participant, whether it describes the participant, and allowing oneself to become caught up in a given train of thought’, the verbalising, self-scrutinising and discursive self, is associated with medial prefrontal cortex in both hemispheres, as well as left hemisphere semantic networks; whereas the ‘experiential’ self, the ‘self in the present moment’, the self ‘sensing what is occurring in one’s thoughts, feelings and body state, without purpose or goal, other than noticing how things are from one moment to the next’, the self that is recruited by mindfulness, is associated with widespread right hemisphere activations (see Chapter 28). These forms of self are usually integrated, but can be dissociated by experts in mindfulness, with the first diminishing, and the second increasing.⁹⁰

My goal throughout this section of the book is to determine how in touch each hemisphere is with reality. It is an important observation, then, that the boundaries of the self,⁹¹ and the coherence of the self over time, are maintained by the right hemisphere.⁹² In right hemisphere damage, and

not uncommonly in schizophrenia, subjects can lose the coherent sense of a self, and even feel themselves melting into another person, so that parts of their own and other bodies become confused – which leads us to how the perceptual world changes when there is damage to the right hemisphere.

The right hemisphere seems embedded in the world, whereas the left hemisphere is intrinsically abstracted from the world. It is just less ‘in touch’. If so, what results when the right hemisphere is no longer available to correct the left hemisphere’s lack of grasp of perceptual reality?

In a word, pandemonium (see Plate 4).

In the largest systematic study to date of the nature and lateralisation of brain lesions giving rise to anomalous altered perceptions – broadly speaking, to illusions and hallucinations – John Cutting found that right hemisphere lesions are ‘critical’.⁹³ In his analysis of almost 200 cases, 73% were due to right-sided lesions.

While hallucinations are a matter of perception, and delusions are a matter of belief, it is interesting that Braun and Suffren, in their survey of delusional disorders, carried out entirely independently in the same year as Cutting’s, 2011, found exactly the same proportion: 73% due to right-sided lesions.⁹⁴

When one looks at the evidence regarding *de novo* psychosis following temporal lobectomy, the figure is 77% due to right-sided procedures, 23% due to left-sided procedures.

These percentages understate the situation, because the more serious disturbances tend to follow right hemisphere lesions. Take the nature of the perceptual alterations noted by Cutting. In cases with right hemisphere damage there are anomalies of shape, size, three-dimensional status, distance, permanence and emotional value, and disruptions of what can only be described as a sense of ‘reality’ itself. By comparison, in the left hemisphere damage cases there are only two obvious effects: ‘geometrical displacement and changes in emotional value’. In fact the situation is even more striking than Cutting lets on by this formulation, since the displacement is just that, not a distortion; and the only two examples he gives of alteration to emotional value following left hemisphere damage both demonstrate an *increase in the intensity of the sense of reality*.

Visual hallucinations and distortions

Let's begin by looking at visual hallucinations. Two studies looking at a total of 31 visual hallucinations of organic origin (ie, cases in which a brain lesion was discovered that underlay the phenomena) each found that the hallucinations were caused by damage to the right hemisphere in almost 90% of cases.⁹⁵ A study of epileptic foci giving rise to visual hallucinations by Wilder Penfield found that 10 out of 11 were associated with right-sided brain deficits, and 'stimulation produced these illusions only in the minor hemisphere for handedness'.⁹⁶ A further study by the French psychiatrists Pierre Mouren and Arthur Tatossian found that the preponderance of damage to the right hemisphere was 'clear-cut'.⁹⁷ Amongst other cases, they describe a man with a right parieto-occipital lesion who clearly saw, amongst other things, a pine tree that he knew he had cut down five years previously. He also experienced, in keeping with the lesion being in the right hemisphere, disappearance of the left half of his body, and denied he had any illness.⁹⁸

A systematic, but not exhaustive, review of the literature on specifically visual hallucinations to date carried out by myself for these purposes reveals that in those cases (99) where a clear focal lesion can be implicated for a pure visual hallucination, 88% were located in the right hemisphere, and 12% in the left hemisphere.⁹⁹ Three localisable cases involved circumscribed lesions in both hemispheres, and were not included.¹⁰⁰ I have also not here included cases exclusively of metamorphopsia, nor AiWS, the so-called Alice in Wonderland syndrome (both of which are overwhelmingly due to right-sided lesions), because I will be dealing with them separately in the next few pages. Some epileptogenic foci in the left hemisphere interestingly involve visual hallucinations of *words*.¹⁰¹ (Words intruding into visual images are common in schizophrenia.)

On its own, the left hemisphere has problems with the realm of the visual. Distortions of space of all kinds, starting with the simple matter of size, are much commoner after right hemisphere damage,¹⁰² and visual distortions of shape often accompany prosopagnosia (inability to recognise faces), which is almost always a right hemisphere deficit. After a right hemisphere stroke, perception of images or lines may be tilted, either visually, or as a matter of proprioception (by the inner sense of bodily position), or to the sense of touch; as can be imagined, this is distressing and can hinder rehabilitation. It can happen after lesions in either

hemisphere,¹⁰³ but where this is serious it is usually, and where it is in more than one modality almost invariably (94%), a consequence of right hemisphere stroke, commonly involving the parietal area.¹⁰⁴ Interestingly, similar tilt distortions also occur not infrequently in schizophrenia: for example, one subject reported that ‘the houses on the street were all skewed, they no longer stood upright’.¹⁰⁵

Visual distortions are fascinating, but are rendered initially off-putting by portentous names beloved by neurologists. Putting it simply, things can appear transformed in some way (metamorphopsia), or the wrong size (dysmetropsia or dysmegalopsia) – that is to say, too large (macropsia) or too small (micropsia). They can also appear too far away (teleopsia) or too close (pelopsia). That’s most of it. Metamorphopsia is a handy umbrella term.

In one series involving visual distortions, 10 out of 13 cases had right posterior involvement.¹⁰⁶ Other cases of metamorphopsia have been generally due to right-sided dysfunction, very generally in the right occipital region (though in the right precuneus, an area of the superior parietal lobe bordering on the occipital lobe and also involved in vision, in one case);¹⁰⁷ and in some cases it is accompanied by other phenomena which are notably commoner after right hemisphere lesions. Reviewing cases of metamorphopsia, Tanja Nijboer and colleagues found that they are either unilaterally right-sided or, if not, bilateral.¹⁰⁸ As far as I know, only three cases have been reported following a *left* hemisphere lesion only, and in one of those the effects were limited to blurring of vision of objects in the right side of space.¹⁰⁹ Following a case report and literature review, Francesca Frassinetti and colleagues conclude: ‘we maintain that lesions causing dysmetropsia [metamorphopsia] involve the inferior portion of the right parastriate area.’¹¹⁰ That is to say, visual distortions are dependent on right, rather than left, posterior cortical dysfunction.

Alterations in size are known to be commoner after right than after left temporal lesions.¹¹¹ In the series reported by Mouren and Tatossian, what they call *microtéléopsie* (things appearing small and distant) was almost always associated with abnormalities in the right occipital region. One man had to keep braking when cycling because the road and the surroundings seemed small and very far away, as if stretched out into the distance. The door to his flat seemed too small to enter, and he went away rather than try

to go in, troubled as he was by the awareness that this was an odd thing to do. He described it as ‘like looking down the wrong end of a telescope.’¹¹²

Micropsia in just one half of the visual field, known as hemimicropsia, is a relatively common subset. In nine cases reported in eight separate studies, it followed a right hemisphere lesion in every case (one case was bilateral), and the visual field affected was, with the exception of this last case, the left (see note for details of pathology).¹¹³

A patient with left hemimicropsia following a right occipital lesion, when asked to draw a butterfly, exhibited a compensatory enlargement of the left half of the butterfly. When asked about it she was not aware of the discrepancy, because only by drawing it enlarged could she make it look – to her – the ‘normal’ size.¹¹⁴

One curious phenomenon involves distorted perception of faces only – everything else is spared. It is sometimes called prosopometamorphopsia. Most such cases involve the right hemisphere, which is not surprising since face perception is largely dependent on the right hemisphere.¹¹⁵ And in two separate case reports, following a right hemisphere infarct, the patient reported, intriguingly, that the faces of family members looked distorted, while faces of other people looked normal.¹¹⁶ Interfering with the right inferior occipital gyrus by electrical stimulation produces transient distortions in faces experimentally.¹¹⁷

Occasionally there is one-sided prosopometamorphopsia, usually a form of hemimicropsia or hemimacropsia that affects faces only (see Plates 5[a] & 5[b]). Seven separately reported cases of left-sided prosopometamorphopsia for faces only were due to right hemisphere dysfunction.¹¹⁸ One woman found that, after a right posterior stroke, ‘when she looked into a mirror ... the left half of her face’ – she meant by this the part in her left visual field – ‘looked smaller than the right’.¹¹⁹ Other objects, meanwhile, looked normal, irrespective of field. One subject with a right posterior infarction saw images that were distorted, including seeing half of people’s faces, in the left field of vision, melt away ‘like clocks in a Dali painting’ (see Plate 6[a]).¹²⁰

Four cases of right-sided prosopometamorphopsia nonetheless still involved *right-sided* pathology.¹²¹ One girl saw her family as looking older than they were; another woman saw ‘any minute asymmetry as grossly distorted’; a third found that ‘the left half of the faces of people walking on

the street in the opposite direction appeared distorted; they looked like monsters'; and a fourth case reported distortion of the left eye only, and of the eye in human faces only: 'faces resembled the paintings of Picasso'. These cases reinforce the observation that metamorphopsia, whether of the right or left side of space, is usually produced by disturbances in the right hemisphere.¹²² This is possibly because the right hemisphere takes care of reality for both 'halves' of the world, with the consequence that the manifestations may appear on either side.

Unilateral prosopometamorphopsia attributable to left, rather than right, hemisphere hypofunction has been described, to my knowledge, in only four patients to date.¹²³ But, as Luigi Trojano and colleagues write, presenting one such case:

Our proposal is consistent with both neuropsychological and neurofunctional data demonstrating a right hemispheric lateralization for face processing ... We speculated that early stages of face perception proceed in parallel in the two hemispheres and only at late stages the right hemisphere *integrates information gathered from both parts* of the stimulus to build up an unitary face representation ... ¹²⁴

This model is supported by subsequent research.¹²⁵ Infarctions or tumours of the corpus callosum resulting in prosopometamorphopsia are almost invariably in what is called the splenium, the most posterior part of the corpus callosum. They almost always produce left-sided distortions: a review of the nine published cases to date found that seven out of eight of the right-handers experienced disturbance in the left field; and the one left-hander experienced disturbance in the right field.¹²⁶

Finally, there is a single report of both metamorphopsia and Cotard's syndrome occurring together, caused by laminar necrosis, a form of cell death, in the posterior right hemisphere.¹²⁷

It is notable that, while these visual distortions following brain insults are not common, very similar visual illusions and hallucinations *are* common in patients with schizophrenia – occurring in more than a quarter of cases.¹²⁸ These include every category that Cutting found in right hemisphere damage: shape, size, three-dimensional status, distance,

permanence, emotional value, and disruptions of the sense of ‘reality’ itself. I will discuss at length in Chapter 9 the overlap between right hemisphere deficits and schizophrenia.

Below are some illustrative examples of each, taken from the accounts of subjects with schizophrenia:

- *Shape:*

‘I saw a man who suddenly had the teeth and nose of a rabbit’ ¹²⁹

‘For short periods I kept seeing things criss-cross, weirdly scrunched up to one another’ ¹³⁰

‘Houses float, walls move in on her and then drift away’ ¹³¹

‘Objects in odd proportions, street seems to tilt, walls of building closing in’ ¹³²

‘The houses were all so lopsided, they didn’t stand straight’ ¹³³

‘When I look down at the lower part of my body, it constantly feels twisted and displaced to the left, compared to the rest of the body.’ ¹³⁴

- *Size:*

‘The furniture seemed warped and small, the room long and wide’ ¹³⁵

‘People were changed – one day outsize, another all small again’ ¹³⁶

There may also be so-called Lilliputian hallucinations, a quite distinct phenomenon, in which subjects see miniature objects or persons (‘persecutor dwarfs’) either in objective space or invading the body; there have been four reports to date in schizophrenia ¹³⁷

- *Three-dimensional status:*

‘External world ... like a two-dimensional transparency’ ¹³⁸

‘She could not see except in outlines, grey against grey, and with no depth, but flatly, like a picture’ ¹³⁹

‘the flat, grey, blurred, and two-dimensional waste of her vision’ ¹⁴⁰

‘The scenery seems too still and flat, like a picture postcard. I have lost my depth perception and am consequently struggling to maintain a sense of reality. I feel that if I were to reach up and to grab the corner of my field of vision, I could tear it away from its base, as if it were a sheet of paper on a picture calendar’ ¹⁴¹

‘People are of one dimension – cardboard cut-outs’ ¹⁴²

- *Distance:*

‘I see everything as through a telescope, smaller and at a very great distance, yet not smaller in reality but more in the mind ... less related to each other and to myself as it were ... everything is far away’ ¹⁴³

‘Everything was ... so far away’ ¹⁴⁴

‘One day, for many hours, a malaise infects me. Faint spatial irregularities distort my perceptions, deepening stairs and telescoping school corridors’ ¹⁴⁵

‘My eyes seem to have trouble focussing; I can no longer make out anything except what lies directly in my path, as if the world were far away, at the end of a long grey tube’ ¹⁴⁶

- *Permanence:*

‘He experienced the sudden disappearance of his wife from his visual field. One day later the waitress suddenly disappeared from his view ... All other elements of the scenes were intact, undistorted, and normally illuminated. Even the chair in which the patient’s wife sat and the counter behind the waitress remained unchanged. Within 10–15 seconds, both subjects had reappeared as suddenly as they had disappeared’ ¹⁴⁷

- *Emotional value:*

‘I am starting to feel pretty numb about everything because I am becoming an object and objects don’t have feelings’ ¹⁴⁸

‘Flies and insects [were] like supernatural things bearing messages’ ¹⁴⁹

- *Sense of reality:*

‘During the last week, the acute attacks of unreality began again when everything appeared vast, detached, brightly lighted ... I had lost real contact with Mama. I always watched her come with joy, but she seemed unreal, artificial’ ¹⁵⁰

There are also other right hemisphere deficit illusions that are experienced in schizophrenia, such as palinopsia (‘visual trails’):

I sometimes see abstract patterns I have seen some time before. They persist for days at the same place in my visual field; when I move my head, they follow ... [in another case] Sometimes I still see things that aren’t there anymore ... They remain before my eyes for a while. It’s like a visual echo. ¹⁵¹

This is also paralleled, since it is not just a perceptual phenomenon, in the process of thinking:

When the next thought comes along the residue of the last one is still there. Vague impression of all thoughts lingering in my mind at once. Several thoughts demanding attention at the same time. My consciousness has limbs stuck in different ideas. ¹⁵²

Limbs ‘stuck in different ideas’? How amazing is that as an expression of simultaneous virtualisation and fragmentation of the lived body?

And there are many illusions of fragmentation:

‘I have to put things together in my head. If I look at my watch I see the watch, watchstrap, face, hands and so on, then I have got to put them together to get it into one piece.’¹⁵³

Prosopometamorphopsia (distortion of faces), particularly unilateral prosopometamorphopsia, is also well recognised in schizophrenia. According to Gross and Huber’s classic review of sensory disturbances in schizophrenia, the commonest visual distortions were those of the human face and form:¹⁵⁴ for example, ‘the face of my sister-in-law, normally so slender, was broad and red, and her mouth warped’.¹⁵⁵ Many of these involved just half the face: ‘the left half of my husband’s face seemed suddenly quite different, so sad and so serious, quite different from the right half – as if my husband had been divided in two.’¹⁵⁶

Six schizophrenic patients in their study also exhibited a related phenomenon: on looking in the mirror they saw their face as deformed, masklike or completely unrecognisable.¹⁵⁷ Eight others saw things twisted or on an incline: a buckling, bowing or bending.¹⁵⁸

The archives of the Bethlem Royal Hospital contain a drawing by a subject with schizophrenia which stands as a good example of lateralised prosopometamorphopsia (see Fig. 10).¹⁵⁹ The subject saw a nurse’s right eye alone horribly distorted.

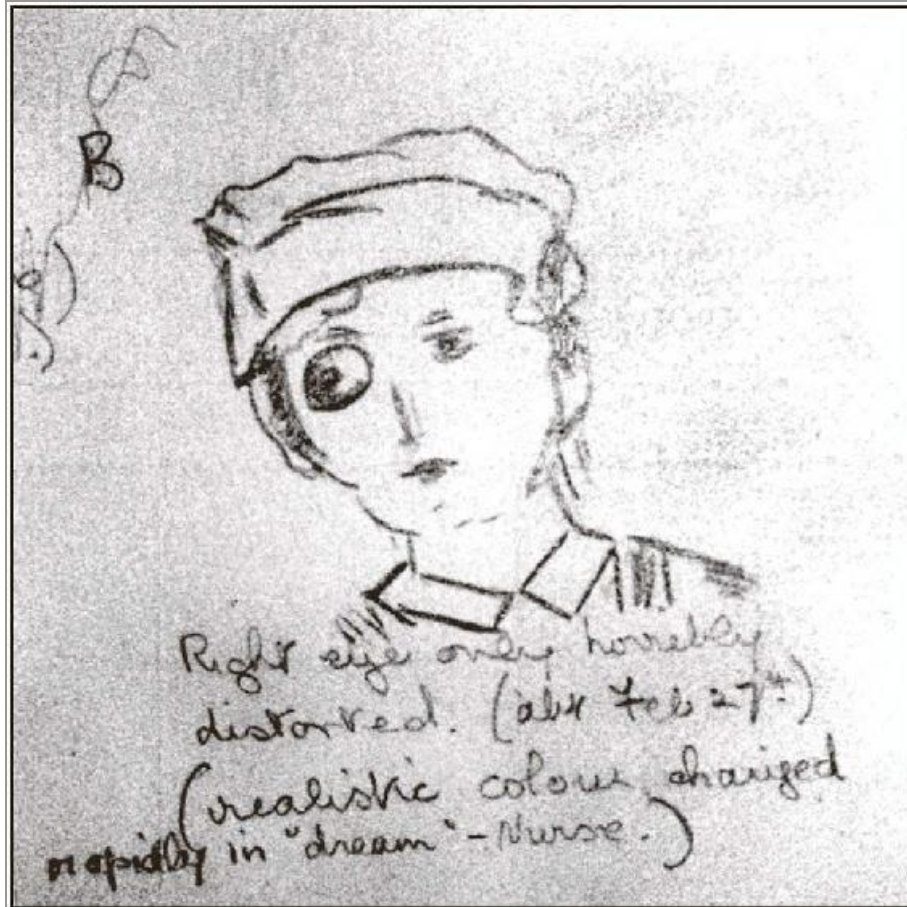

Fig. 10. 'Right eye only horribly distorted':
hemiprosopometamorphopsia (from the Bethlem Royal Hospital
archives, B3 352)

Then there is the phenomenon rather more poetically called 'Alice in Wonderland syndrome', a term which is often used rather liberally to refer to almost any combination of visual misperceptions. It should strictly involve, however, not just, or even primarily, visual disturbances, but disturbances of the perception of one's own body and the experience of time.¹⁶⁰ Accounts of the true syndrome are not common, but, as mentioned, point in almost all cases to disturbances in the right hemisphere.¹⁶¹

Fig. 11. 'Curiouser and curiouser': Alice-in-Wonderland syndrome, somatic effects (from Sir John Tenniel's illustrations to Lewis Carroll's Alice's Adventures in Wonderland, 1865)

The syndrome was first so named in the 1950s by a psychiatrist at the Littlemore Hospital in Oxford, John Todd, who reported a series of six cases. In Lewis Carroll's story, it will be remembered, Alice's body shrank after drinking from a bottle labelled DRINK ME, and became so large, after she ate a cake labelled EAT ME, that she almost touched the ceiling:

'Curiouser and curiouser!' cried Alice ... 'now I'm opening out like the largest telescope that ever was! Good-bye feet!'

However, as Todd points out, Alice was also

sometimes aware of changes of an altogether more subtle nature. Thus, there were occasions when she was conscious of some intangible change in herself and her environment. There were also times when she addressed herself as though she were two people, and others when she puzzled over her own identity ...

Alice also experienced slowing of time and motion, which, as we have already established, usually points to a right hemisphere disturbance:

Either the well was very deep, or she fell very slowly, for she had plenty of time as she went down to look about her and to wonder what was going to happen next ... Down, down, down. Would the fall never come to an end! 'I wonder how many miles I've fallen by this time?' she said aloud, 'I must be getting somewhere near the centre of the earth ...'

In *Through the Looking-Glass* there are also examples of distortions of the perception of space and time, such as being aware of the body moving fast without making progress through space – as in running with the Red Queen.

*Fig. 12. ‘In my kingdom, you have to run as fast as you can just to stay in the same place’” Alice-in-Wonderland syndrome, temporal effects (from Sir John Tenniel’s illustrations to Lewis Carroll’s *Through the Looking-Glass, and What Alice Found*, 1871)*

It is thought that Charles Dodgson, the ‘real’ Lewis Carroll, was describing, or at any rate building on, his own experiences with either migraine or temporal lobe epilepsy, each of which can give rise to metamorphopsia, as well as disturbances of time and motion perception – the essence of the Alice in Wonderland syndrome.¹⁶²

Another British psychiatrist, Stanley Coleman, had a couple of decades earlier discussed the case of a woman who would, ‘like Alice in Wonderland’, sometimes feel that she was shorter, sometimes that she was taller than she used to be.¹⁶³ This woman was developing schizophrenia, which, as the reader will recognise, is often accompanied by abnormal thoughts and experiences that are otherwise found in right hemisphere damage. And shortly before Todd’s description, the American neurologist Caro Lippman also described seven cases, including that of a middle-aged woman who suffered recurrent headaches with nausea, vomiting, and visual disturbances, presumed to be migraine. At such time she experienced

the illusion of being much taller than I actually am, in relation to ordinary objects. My head would seem far above my hands, far above table tops, etc. At other times, I seem to be ('astrally', I suppose you'd call it) detached from and above my physical body, to be able to observe it and make mental notations concerning it as a separate entity.¹⁶⁴

Here she describes, as well as elongation of the body, autoscopy. Two other patients of Lippman experienced similar elongation:

(First patient) It was at these times that I experienced the sensation that my head had grown to tremendous proportions and was so light that it floated up to the ceiling, although I was sure it was still attached to my neck. I used to try to hold it down with my hands ...

(Second patient) I get all tired out from pulling my head down from the ceiling. My head feels like a balloon; my neck stretches and my head goes to the ceiling. I've been pulling it down all night long.

Another experienced feeling 'about one foot high', while yet another patient actually referred to her experiences as 'the Tweedle-Dum or Tweedle-Dee feeling', perhaps prompted by the feeling of being, not just shorter and fatter, but in some sense twofold. Intriguingly, another reported size alterations occurring just on one side at any one time:

Today my body is as if someone had drawn a vertical line separating the two halves. The right half seems to be twice the size of the left half. I wonder how I am going to get my hat on when one side of my head is so much bigger than the other. After a few minutes of feeling large, the right half seems to shrink until it is smaller than the left. This process has been coming and going all day long ...

Neither Coleman's nor Lippman's accounts give clear indicators of laterality.¹⁶⁵ Only two of Todd's six accounts yield possibly lateralising signs, both suggesting right hemisphere pathology. One subject experienced:

transient feelings of unreality, of depersonalization, of growing small (half her real size), and of duality. The latter takes the form of an invisible alter ego: 'I become aware of an invisible double stationed a yard away on my *left*. This shadowy double seems to contain my mind.'

Another complained of:

a recurrent morbid urge to strangle herself, or anyone else who chanced to be at hand during the attacks. In addition, she was periodically conscious of illusory distortions of her body. On these occasions her head would feel three times its normal size, or her legs so shortened that her feet seemed to be attached just below her knees. Without warning, she would be overwhelmed by feelings of unreality of such intensity that she was compelled to look in a mirror to confirm her presence in the room. Sometimes her *left* arm and breast would suddenly *lose their personal significance; they no longer seemed to belong to her*. Not infrequently she noticed an illusory diminution in the size of objects or persons, which at times assumed Lilliputian proportions (micropsia). [166](#)

The loss of personal significance and sense of belonging, together with the left-sided phenomena, suggest right hemisphere pathology.

Since these early case reports, there have been, it has been claimed, as many as 100 or more further published accounts of Alice in Wonderland syndrome (or AiWS). The number very much depends on what counts as AiWS, and would be far lower if there were any degree of stringency to the criteria. In addition, many of the cases involve global infective encephalopathies, migraine or psychiatric conditions with no localising features, as well as drug reactions. I know of 15 cases in which it was possible to identify a focal abnormality: of these, 14 involved right hemisphere dysfunction (two being bilateral), and only one involved left hemisphere dysfunction alone. In my view this latter case is quite clearly not, in fact, a case of AiWS: the subject merely saw alterations of colour cast and 'scintillations'. This would be in keeping with the principle that left hemisphere involvement on its own leads usually to less dramatic

alterations in the nature of reality – hardly, in this case, alterations in reality at all (see note for details of all cases).¹⁶⁷

In three recent reviews of the literature on the syndrome, laterality is mentioned only occasionally in passing, and there was no attempt in any of them to assess differences of laterality in any systematic fashion, demonstrating rather vividly the continuing neglect of the importance of laterality in neuroscience research.¹⁶⁸

Auditory hallucinations

An analysis of a large number of previously published cases of auditory hallucinations where they were due to unilateral brain lesions shows that in almost 100% of such cases the lesions are right-sided.¹⁶⁹ This was independent of sex, age, verbal or non-verbal content of the hallucination, or any other discriminable factor. A subsequent study of 641 stroke patients found that auditory hallucinations were rare in that population, but that every single case involved damage to the right temporal lobe.¹⁷⁰ The commonest form of hallucination in psychotic patients is auditory, and most of these are found in schizophrenia and mania, conditions both of which resemble, in different respects, a left over right hemisphere imbalance.¹⁷¹

So much for the site of damage. But where do the auditory hallucinations themselves originate? Do they come from the abnormal right hemisphere? Or from the intact left hemisphere, now that it no longer has countervailing input from the right hemisphere to orientate it to reality? One possibility is that they are the left hemisphere's verbalisation of thoughts originating in the right hemisphere.¹⁷² In a study of 87 patients, a conflicting stimulus delivered to the right ear/left hemisphere interfered with auditory hallucinations, but did not when delivered to the left ear/right hemisphere, suggesting that the left auditory cortex may be the seat of auditory hallucinations.¹⁷³ In line with this, a significant increase in relative EEG power was observed in the left, but not in the right, auditory cortex during auditory hallucinations.¹⁷⁴ A meta-analysis of studies that used rTMS to suppress the left temporoparietal region revealed that this was an effective treatment for auditory hallucinations.¹⁷⁵ This all goes to suggest that the problem in right hemisphere injury is that there is no longer anything to counterbalance the left hemisphere's alienating, objectifying

tendency, nothing to orientate the subject to reality. This interpretation would be in line with the report of a man who experienced auditory hallucinations for the first time *after* right temporal lobectomy.¹⁷⁶ Even articulations of the subject's own thoughts then appear somehow alien.

There is a distinct category of auditory hallucinations known as musical hallucinations. These are not delusional in the way that auditory hallucinations are. The majority of these are due to right hemisphere lesions; one study suggests that they can originate in abnormal activity in the left hemisphere.¹⁷⁷ A review of 46 cases by German Berrios concluded that right hemisphere pathology was 'over-represented'.¹⁷⁸ Another review finds that musical hallucinations point generally to the same right hemisphere deficits.¹⁷⁹ Case reports of musical hallucinations in which an organic pathology can be localised to one hemisphere or another, reveal 12 due to right hemisphere (usually temporal lobe) pathology,¹⁸⁰ six due to a left hemisphere focus of pathology,¹⁸¹ and one due to bilateral temporal lobe pathology.¹⁸² However, a review of the Mayo Clinic's records, which unearthed 393 cases of musical hallucinations, involving either hemisphere, found no statistically significant hemisphere difference.¹⁸³

Olfactory and gustatory hallucinations

No overview of lateralisation in olfactory hallucinations has been undertaken, possibly because cases in which brain localisation is possible are rare. Studies of lateralisation of normal olfactory function favour the right orbitofrontal area, as we have seen. I can find only five reported cases of olfactory hallucination to date for which a lateralised brain lesion can be identified: four of these were in the right hemisphere (the left-sided case was female, handedness not given).¹⁸⁴

I can find only three cases of gustatory hallucinations in which lateralised pathology was identifiable. All three were due to pathology in the right temporal region.¹⁸⁵

Olfactory and gustatory hallucinations occur fairly frequently in schizophrenia, with a lifetime prevalence of between 15% and 35%.¹⁸⁶

Tactile hallucinations

Most haptic (tactile) hallucinations are drug-induced or form part of a 'non-organic' psychiatric illness, and are therefore not localisable. Where they are associated with localisable, unilateral pathology, almost all abnormalities of the sense of touch seem to follow right hemisphere damage, as a range of imaging and neuropsychological studies has shown.¹⁸⁷ I am aware of only three cases involving the left hemisphere, of which one was bilateral. All three cases were female and handedness was not given.¹⁸⁸ Haptic hallucinations are not uncommon in schizophrenia.¹⁸⁹

I am sometimes asked whether the experiences of people taking hallucinogenic drugs are due to right hemisphere 'release'. I am very doubtful of this. There is very little direct evidence, but on first principles, it seems more likely that, to the extent that lateralisation is a significant factor, they are caused by suppression of the right hemisphere. What little evidence exists supports this interpretation. In a now famous study by Serafetinides in 1965 – one that is (sadly from the purely scientific point of view) very unlikely to be repeated – subjects with either right or left temporal lobe epileptogenic foci were given LSD both before and after temporal lobectomy for their epilepsy. The hallucinations were significantly more marked in the right hemisphere-damaged subjects than in the left hemisphere-damaged subjects and *continued to be so after temporal lobectomy*; in other words they remained elevated after the right temporal lobe was actually removed.¹⁹⁰ The mean perceptual disturbance scores were 17.33 pre-operatively for right hemisphere damage (left hemisphere predominance), and were still 12.10 after removal of the right temporal lobe altogether; by contrast they were 8.18 for left hemisphere damage (right hemisphere predominance), and fell to only 2.82 (almost abolished) after removal of the left temporal lobe. This implies that hallucinations are more often due to right hemisphere than left hemisphere dysfunction.

Almost all extraordinary distortions of reality follow from right hemisphere damage. More than this, it is not just hallucinations and misperceptions, but delusions, distortions of judgment and belief, that are, as I will demonstrate in the next chapter, associated with the left hemisphere. In fact, hallucinations may themselves result from failures of judgment. We all see faces in the foliage on trees, but most of us disregard the likelihood that these are secret agents sent to spy on us. Equally, we all experience people we know as different on different occasions, but few of us conclude that they are not really human, but zombies or machines. It

seems that when the right hemisphere's guidance is lacking, we are much more likely to make both over-credulous, and over-sceptical, judgments on reality.

SUMMARY

In every sensory modality the right hemisphere appears to have an advantage over the left when it comes to primary perception. Perceptual distortions and hallucinations in each sensory modality are strongly associated with right hemisphere dysfunction. Thus, as far as both attention and perception go, the right hemisphere is a more important guide and a more reliable one to the nature of reality. This is in keeping with the roles of the hemispheres diverging over evolution, as described in Chapter 1.

JUDGMENT

Perception is a judgment, but one that is unaware of its reasons, which is as much as to say that the object perceived gives itself as a whole and as a unity before we have grasped its intelligible principle.

—*Maurice Merleau-Ponty*¹

WE WILL BE LOOKING AT THE ROLES OF THE TWO HEMISPHERES IN THE normal process of reaching beliefs and making judgments throughout Part II, since such an examination is fundamental to our aim of knowing when we are more, or less, likely to be deceiving ourselves. Here, then, I will concern myself with what happens when the process itself has clearly gone awry: when we are prey to delusions.

We have seen that most hallucinations are due to right hemisphere damage or dysfunction. What the research literature to date suggests is that nearly all delusions, as well – in particular the more extravagant ones – are due to right hemisphere damage or dysfunction.² Distinguishing delusions (distorted reality judgments) from hallucinations (distorted perceptions) is to some degree arbitrary, since misperceptions can give rise to misbeliefs, and misbeliefs give rise to misperceptions. Added to which, all perceptions involve a judgment undertaken before we are aware of it. We don't see a shape, a texture, a bunch of colours, and only then deduce 'a tree'. We see the tree whole and immediately, because somewhere way below

consciousness we are discriminating what fits best in the context in which we find ourselves.

I will therefore look at the various syndromes that follow as they span abnormal perception, abnormal belief and abnormal judgment, before moving on to what are more clearly matters of judgment alone. Our categories are sharp; life is blunt.

HEMISPHERIC DIFFERENCES IN PATHOLOGIES OF JUDGMENT

What we find in this chapter is that, if the left hemisphere is not frankly deluded, it is clearly at sea, and the right hemisphere is its reliable anchor in reality. I'll wager that is not what you have heard to date – so does that sound a bit extreme? Let's take a look.

A review by Andrew Young in 2000 found that 'diverse though they may be, delusional beliefs tend to follow brain injury affecting the right cerebral hemisphere ... every delusion discussed so far [in his review] has been shown to be more frequent after right- than after left- sided brain damage'.³

People with right hemisphere strokes may develop schizophrenic-like delusions as a result of their lesions. A comprehensive search of the literature to 2018 revealed 106 cases of such delusions following right hemisphere stroke (though at least two, perhaps three, cases that would appear to have met criteria may have been overlooked – see notes).⁴ Of these 106, only 19 occurred after left hemisphere stroke. Psychosis may be precipitated by right brain injury or by surgery, especially after heart surgery, possibly because this may compromise blood flow to the right hemisphere.⁵

It does seem that there is something intrinsically prone to delusion about the left hemisphere. Nikki Marinsek and colleagues, including Mike Gazzaniga, in another paper write: 'Delusions may ... arise when the left hemisphere's tendency to explain goes awry; indeed, delusional disorders are characterized by excessive inference making and the tendency to prematurely jump to conclusions.'⁶ And Orrin Devinsky:

The unchecked left hemisphere unleashes a creative narrator from the monitoring of self, memory, and reality by the frontal and right hemisphere areas, leading to excessive and false explanations. Further, the left hemisphere's cognitive style of categorization, often into dual categories, leads it to invent a duplicate or impostor to resolve conflicting information. Delusions result from right hemisphere lesions. But it is the *left hemisphere that is deluded*.⁷

One of the reasons schizophrenics are deluded is their tendency to jump to conclusions without weighing up overall whether these conclusions are probable.⁸ This is thought to be because of a need for closure – a tendency to prefer an answer, irrespective of its plausibility, to ambiguity and uncertainty.⁹ This is a tendency that is also reflected in the culture of modernity: it encourages us all to rush for closure. When told that there are 125 sheep and five dogs in a flock, and then asked ‘How old is the shepherd?’, three out of four schoolchildren will produce a numerical answer, rather than reply that ‘there is not enough information’.¹⁰

If you combine this need for closure, exaggerated in schizophrenia and the isolated left hemisphere, with the paucity of reliable experience available in the absence of a properly functioning right hemisphere, the picture becomes understandable. In an interesting paper on the nature of delusion, Braun & Suffren posit a model

not so much based on perceptual or cognitive deficits after right hemisphere damage as on cognitive propensities, specifically excessive inferencing (especially jumping to conclusions) and excessive reference to the self, due to left hemisphere overactivity.

Their conclusion is that ‘most cases of delusion’ are due to left hemisphere overactivity combined with right hemisphere underactivity.¹¹ Since the relationship between the hemispheres is a dynamic one of reciprocal inhibition, it is in a sense irrelevant whether what happens is that the right hemisphere is underactive, or the left hemisphere is overactive, since the effect in either case is the same: once the reality-testing, reality-congruent, right hemisphere is overwhelmed, there is nothing to stop the left hemisphere going off on one. Delusions have consistently been linked to *either* right hemisphere dysfunction *or* left hemisphere overactivity (or both).¹² When the left hemisphere has to depend on its partial understanding of the world, it may ‘create explanations that are incorrect, inappropriate, or even bizarre’.¹³

What happens is not that reality is primarily shaped by the left hemisphere, albeit in delinquent fashion, and that this is then knocked into a realistic shape by the thought police of the right hemisphere, but that reality is primarily shaped by the right hemisphere. So when the right hemisphere

is malfunctioning, the left hemisphere is relatively at a loss. In the normal state of affairs, the world is construed realistically by the right hemisphere, and a highly stylised version of it is then taken up and worked with by the left hemisphere in ways that may or may not bear much relation to reality, from which it is always operating at a remove. This remove is OK up to a point, provided the left hemisphere is properly tethered to the right hemisphere. The problem comes with right hemisphere damage, when there is no countervailing balance – and then the result is, indeed, pandemonium.

I mentioned that Braun & Suffren ¹⁴ found that, where delusional disorder was associated with a unilateral cerebral lesion, in 73% cases it was in the right hemisphere. This is in accord with the findings in many other studies suggesting that neurological patients with delusions commonly have lesions in the right hemisphere alone, or both hemispheres, rarely just in the left hemisphere.¹⁵ Psychosis is common after removing the right temporal lobe, more rarely after removing the left.¹⁶ Right hemisphere damage much more commonly leads to psychotic phenomena than left hemisphere damage (approximately 6:1).¹⁷ Delusions in Alzheimer's disease have repeatedly been shown to be associated with hypofunction of the anterior right, rather than left, hemisphere.¹⁸ The right dorsolateral prefrontal cortex (malfunctioning in schizophrenia) is the most important part of the brain for testing our theories against experience.¹⁹ Max Coltheart, the author of a number of important more recent papers on the area, draws attention to the fact that 'the region of the brain specifically involved in hypothesis evaluation ... is the right lateral prefrontal cortex', and that delusions occur when it is not fully operative.²⁰

This is not really surprising if one just thinks about the phenomenology. The main features of delusions – poor reality testing, incorrigibility, and unwarranted subjective certainty²¹ – are all features of the left hemisphere's world. Indeed, one way of seeing the variable ratio of right to left damage in delusions is to look at the extreme nature, and the incorrigibility, of the delusion. The more extreme, and the more incorrigible, the delusion, the more likely it is to be due to right hemisphere dysfunction and a free-wheeling left hemisphere. Thus, for example, anosognosia (denial of a deficit) is most commonly due to right hemisphere damage, but somatoparaphrenia (thinking that bits of your body don't even belong to you) is almost always so.

Neglect

We are already familiar with this phenomenon, which involves judgment. Damage to the right parietal lobe often results in a patient's losing the left half of space. Though damage to the left parietal lobe can, infrequently, produce something like this deficit in the right half of space, when it does so, the impairment is much less marked and more transient,²² and 'the vast majority of patients with spatial neglect suffer from right hemisphere damage.'²³ To put that assertion in context, in a series of 59 patients with hemineglect assembled by Henri Hécaen, 55 had right-sided lesions; of the four with left hemisphere lesions, three were left-handed.²⁴ In a further series of 57 patients reported by Hécaen, 56 had right hemisphere lesions.²⁵ Hécaen – one of the most revered names in the history of neuropsychology – could be mistaken, but probably not by any amount that is going to change the view that this phenomenon is highly characteristic of damage to the right hemisphere, not the left.

Anosognosia, asomatognosia, somatoparaphrenia, and anosodiaphoria

I can pass over these here, because you have heard enough about them in the previous chapters, and we have already established that the first (denial of a deficit) most commonly is, and the last three (failure to recognise body parts, attribution of a body part to another person, and incongruous indifference to a deficit) almost invariably are, associated with right hemisphere deficits.

It has been suggested that the strength of the association of anosognosia with right hemisphere damage might be artificially inflated by the fact that after left hemisphere stroke many patients are aphasic, and therefore not articulate enough to deny their paralysis, unlike right hemisphere stroke patients. This was addressed by a study in which eight normal subjects had one hemisphere at a time knocked out by an injection of sodium amytal into the carotid artery. In each case, the subject developed a contralateral hemiplegia – a weakness or paralysis on the other side of the body – within five seconds. Afterwards, all eight recalled the right-sided hemiplegia; not one recalled the left. In other words, with the left hemisphere knocked out

they were fully aware of the contralateral deficit; with the right hemisphere knocked out, they were completely oblivious of it.²⁶

Prosopagnosia

Prosopagnosia (inability to recognise faces) almost always implies damage to the right hemisphere, especially the right temporal lobe.²⁷ A review paper by Hécaen & Angelergues presented four cases of prosopagnosia, all with right hemisphere disturbances, and reviewed a series of 22 additional cases, of which 20 involved the right hemisphere (one of those that involved the left hemisphere was left-handed).²⁸ Subsequently Landis and colleagues presented six new cases, all with only right-sided lesions; and reviewed the literature, concluding in favour of the view that a right hemisphere lesion alone is enough to produce prosopagnosia.²⁹ Transient prosopagnosia can be induced in normal subjects simply by disrupting the function of the right anterior fusiform gyrus.³⁰ The left temporal lobe is involved in putting a *name* to a face; but by contrast the recognition of the face as a face, as familiar, and as a particular person, as well as the understanding of its expression – all that is dependent on the right hemisphere.³¹

In a study examining responses to faces presented in one visual field at a time, identifying a face in the right visual field may be associated with activity in the left fusiform area, but only when the face has previously been processed by the right hemisphere, not when it has been processed only by the left: ‘these results imply that facial identity information is transferred from the right hemisphere to the left hemisphere.’³² Incidentally this underscores the value of lesion studies and callosotomy studies, since, in studies of the intact brain, information is being ‘promiscuously’ shared, in a way that makes differentiation more difficult.

In general this ‘quintessential example of hemispheric specialization’, as the researchers put it, was bound to be the case, if only because of the manifest superiority of the right hemisphere at understanding complex wholes, rather than cataloguing a few outstanding features – a mole, a parting, a big nose, and so on.³³ An exhaustive literature review on abnormalities of person recognition demonstrates the crucial role of right hemisphere regions, especially temporal, but also parietal, occipital and

frontal, for person recognition *in any modality* – by face, by voice and so on. Once again, please note that the effect can occur with dysfunction in a wide variety of locations, but almost always within the right hemisphere. Too narrow a concern with one region only may obscure a highly robust hemisphere difference, unless analysis takes this into account. Only recognition of personal names was clearly left hemisphere-dependent. ³⁴

Delusional misidentification

This category of delusions, including Capgras and Fregoli syndromes, and reduplicative paramnesia, we have also looked at before. In organic cases of disorders of misidentification it seems that it is almost always due to right hemisphere damage.³⁵ Out of 20 cases reviewed by Hans Förstl and colleagues, in which delusional misidentification accompanied a focal lesion, 19 were right-sided.³⁶ In 41 cases listed by Burgess *et al*, where there was known neurological pathology, only three had no detectable neurological deficit in the right hemisphere, and two of those were cases of confabulation alone (no data on handedness given).³⁷ And in cases where there was no manifest brain damage as such, cases of delusional misidentification showed, nonetheless, right hemisphere deficits on scanning or neuropsychological testing.³⁸ In the words of one review of the subject: ‘It can be seen that the right hemisphere or bilateral lesions were invariably found on neuroimaging, with no exclusively left hemisphere lesions.’³⁹ The most recent comprehensive review of 61 case reports found right hemisphere lesions in 92% of cases.⁴⁰

Lycanthropy, believing one is turned into a wolf, is a rare form of self-misidentification and appears to be associated, where a brain lesion can be identified, only with right hemisphere lesions.⁴¹ This is in keeping with other evidence that all forms of delusional self-misidentification are dependent on right hemisphere deficits.⁴² It also overlaps with Cotard’s syndrome (another right hemisphere deficit syndrome – see below).⁴³

Paranoia

Right hemisphere dysfunction causes a paranoid psychosis as commonly as it does delusional misidentification.⁴⁴ Paranoia is a general term, which in conventional psychiatric classification strictly implies mistaken reference to self ('the police are communicating with me through the TV'), including grandiose and religious delusions (eg, 'I am the head of MI5/Jesus Christ'); but it is usually taken to mean, in accordance with popular usage, undue suspiciousness, rather than grandiosity (which by the way is associated with left hemisphere overdrive, as in mania). Paranoia is a common feature of mental illness, though the qualification 'mental' could be misleading if it seemed to suggest that such illness is not also, inevitably, a brain disorder. Paranoia is especially common, of course, in schizophrenia which, as I have suggested, in many ways resembles a right hemisphere deficit disorder. In four series of cases of paranoia following cerebral insult, and three case reports, totalling in all 35 cases, every single one involved right-sided lesions.⁴⁵ Cases of Alzheimer's type dementia with paranoid delusions had significantly greater losses of volume in the right hemisphere.⁴⁶ And increased perfusion, a proxy for increased activity, of the left temporal lobe may be associated with an increase in suspiciousness.⁴⁷

Such delusions can coexist with otherwise normal critical faculties. I remember a lovely man, a dignified old-fashioned gentleman with a white moustache, always very well-turned out and apparently well able to care for himself, who told me he was distressed because, since a minor right hemisphere stroke, the police had rented the flat next to his and were broadcasting slander about him. In their latest escapade, he told me, they had turned the speakers to the party wall and were sending him messages direct. Why had they done this? I asked. He replied that he had no idea why they were doing it, but that their suggestions had got quite out of hand. What were they saying? 'Doctor, the things they're telling me to do are not only in themselves quite repulsive, but' – here his voice took on a note of sheer incredulity – 'they're *physically impossible*.'

Othello syndrome

This is the name given to one type of paranoid syndrome, delusional jealousy. Those affected become unreasonably convinced that their partner

has been untrue to them. This often results in tyrannical behaviour – never allowing the partner out of one’s sight, secretly monitoring messages, etc. It is not infrequently caused by alcoholism, and can be a dangerous condition for those who find themselves its target. However, alcoholism or no alcoholism, this paranoid psychosis, like others, is almost always consequent on a right hemisphere, particularly right frontal, lesion.⁴⁸ One prospective study found that no delusional thinking of any kind was present in any of 170 patients with left hemisphere stroke, whereas 15 of 190 patients with right hemisphere stroke were deluded; 20% of these had delusional jealousy.⁴⁹ One case report is suggestive of left frontotemporal pathology but unfortunately does not specify handedness.⁵⁰

And indeed jealousy in general is strongly related to right hemisphere damage.⁵¹ This is consonant with the relatively poor performance of the unaided left hemisphere in understanding emotion, mental state reasoning, making moral judgments, and reading body language, quite apart from its role in generating false beliefs and delusions. Fascinatingly, however, this lateralisation would seem to be already present in infants: infants whose left hemisphere was more active than their right hemisphere on EEG exhibited significantly more jealous behaviour than other infants.⁵²

de Clérambault’s syndrome (erotomania)

This syndrome refers to a delusional belief that someone of high status is in love with you – and has taken the initiative in the romance (the usual left hemisphere’s ‘nothing to do with me, guv’).⁵³ Common targets are celebrities, politicians and royalty. Again it can be dangerous for its targets, who may find themselves being stalked: it’s the *Play Misty for Me* phenomenon. In a reported series of five individuals where erotomania was associated with brain damage, the damage was in every case right-sided.⁵⁴ Another woman with multi-infarct dementia believed that the Prince of Wales had proposed marriage, and that she had already been married to, and separated from, the former Israeli Prime Minister Shimon Peres. There were several findings on CT scan but the principal one was a right parieto-occipital infarct.⁵⁵ However, a man with erotomaniac delusions, who had no clear brain lesion, showed left hemisphere slowing on EEG, and one of two cases reported by Martin Brüne and Stefan Schröder showed generalised

white matter lesions, most prominent in the left internal capsule, the other showing a focus in the right hemisphere.⁵⁶

Mirror agnosia

Then there is the mirrored self delusion, where the subject cannot recognise himself in a looking glass: almost all have right hemisphere or bilateral impairment. In a review of 42 cases where organic brain lesions had been identified, 41 involved the right hemisphere, though 32 of these were bilateral; eight had right-sided focal lesions alone, and just one had a left-sided focal lesion (unfortunately handedness is not recorded).⁵⁷ Other cases support a right hemisphere deficit syndrome.⁵⁸ The right dorsolateral prefrontal cortex, parieto-frontal and insular regions seem to have a crucial role in self-recognition,⁵⁹ including recognising one's own voice.⁶⁰

Cotard's delusion

This is a very curious delusion, named after the nineteenth-century French neurologist, Jules Cotard, who was (there is no justice in the history of medicine) the fifth person to describe it, although he gave the first detailed account.⁶¹ In this condition, patients believe themselves to be already dead, and sometimes demand to be buried. A patient I once looked after with Cotard syndrome agreed to my request to take blood, but assured me that I would be disappointed, because there was none in her body, which, she claimed, was already putrefying. As I took her blood, I showed her the syringe: 'There', I said, hoping to reassure her, and perhaps a little triumphantly, 'there's still blood in your arm.' She looked at me absolutely unfazed, and replied, witheringly: 'You put it there'. In those cases where a lesion has been traced, a right hemisphere lesion, usually affecting the temporoparietal area, has been reported in almost every case.⁶²

Is it a coincidence that the left hemisphere has an affinity with all that is lifeless or mechanical? Some subjects with Cotard's syndrome have been known to cut their wrists to prove they have no blood in them.⁶³ The behaviour is reminiscent of schizophrenic patients who believe themselves to be machines, and are known to cut their wrists to see if there is engine oil in them.⁶⁴ The syndrome often overlaps with Capgras syndrome, which is

also strongly dependent on damage to the right hemisphere: one man believed his stepfather was a cleverly disguised robot, and chopped his head off with a chainsaw looking for the batteries and microchips within (see note for other cases).⁶⁵

Some can be florid. A far from typical case involved a 39 year-old Iranian man who believed not only that he was dead, but that he had been turned into a dog – as had his wife. His daughters had been turned into sheep: he could smell his daughters’ ovine urine in the hospital. People were poisoning his tea, but since he was dead this had proved ineffective. Alas, no investigations of the brain were undertaken.⁶⁶ This case shows signs of lycanthropy (see above).

Delusions of infestation

These are what they say they are. They are often delusional interpretations of bodily sensations such as itching or crawling of the skin, though the sensations themselves are usually hallucinatory. They are strongly associated with right hemisphere lesions;⁶⁷ and tactile hallucinations, specifically, are associated, as we have seen, with right hemisphere damage.

Response-to-next-patient syndrome

This is a fascinating syndrome that, while strictly speaking not delusional, demonstrates an aberrant understanding of the world based on left hemisphere attention.⁶⁸ It was first described by Bogousslavsky and Regli: during the period they surveyed, 439 stroke patients were admitted to hospital, 134 with right hemisphere stroke, 198 with left hemisphere stroke and 107 with ‘infratentorial’ stroke (ie, involving the lower part of the brain, below the level of the hemispheres). They found that 8% of the right hemisphere stroke patients – but not one of the left hemisphere or infratentorial stroke patients – carried out actions or answered questions which were addressed to the *patient in the next bed*, even when they had just been through the same actions and questions in their own case; when asked why, they couldn’t explain. The phenomenon was associated with other common right hemisphere stroke sequelae, such as denial and neglect.

The authors describe it as ‘stuck-in-set’ behaviour, which seems reasonable.⁶⁹ Another way of looking at it is, however, that what should be specific to me has become *generalised*.

ALTERED ROLE OF THE BODY

I mentioned that the right hemisphere supports the body schema. One of the most fascinating aspects of this is that an intact body schema is innate, even in those whose body from birth was abnormal. Phantom limb sensations are reported by children who were *born* without one or more limbs.⁷⁰

And it is the body schema that is aberrant in anorexia nervosa, so much so that a person who is in reality grossly underweight, and may be starving to death, sees herself as grotesquely obese. Although not usually classified as a psychotic illness, it is delusional, and other psychotic symptoms are not uncommon; anorexia can also occur in the prodrome of schizophrenia.⁷¹ Schizophrenia and anorexia nervosa are in fact genetically linked, and each is commoner in genetic lineages of the other.⁷²

Quite apart from the clue given by the fact that the body schema lies in the right parietal cortex, in cases where anorexia was associated with a hemispheric lesion, the majority were right-sided; imaging and EEG studies of anorexia nervosa show hypofunction of the right hemisphere; psychological profiles of subjects with anorexia show typical right hemisphere deficits; and in one case a left-sided stroke caused the sudden remission of a patient whose life for years had been dominated by anorexia nervosa.⁷³ A study of eating disorders in dementia showed that they were associated with atrophy in the right, but not left, frontal cortex, anterior cingulate cortex, caudate head and insula.⁷⁴

It makes sense, then, that when changes in the brain lead to changes in bodily appetites, it is usually right-sided. Leaving aside anorexia nervosa, which is much more complex than any simple disorder of appetite, if it can be considered one at all, disorders of appetite have an association with right hemisphere lesions.⁷⁵ Tumours in the right hemisphere are twice as likely to induce profound loss of appetite as those in the left.⁷⁶ Or the reverse phenomenon: Denis Williams describes in detail a case of a young woman who developed a habit of eating 8-inch wax candles after developing a right temporal tumour.⁷⁷ We reported a case of a man who started to both eat and sleep excessively after a right-sided infarct of the thalamus (he also developed a range of other right hemisphere deficit signs, including visuo-

spatial deficits, fatuous affect, inappropriate elation and irritability, and at times paranoid delusions).⁷⁸

There is also something called ‘gourmand’ syndrome, in which there is an out of character preoccupation with food and, often, a strong preference for fine eating, after the onset of a cerebral lesion. Such patients persistently crave fine food despite having apparently normal sensations of hunger and fullness. Of 36 patients reported in the largest review of the syndrome, 34 had lesions in the right hemisphere, in frontal lobe, basal ganglia, or limbic areas.⁷⁹ Many of these ‘gourmand’ patients, unsurprisingly, develop other behavioural changes typical of right frontal damage: they become disinhibited, talk excessively, become more aggressive and impulsive (in fact, food craving may be just an aspect of this wider problem), and lack emotional control. Any likeness to well-known food journalists is entirely co-incidental.

Autoscopy and heautoscopy

Autoscopy is seeing yourself from outside your own body, usually floating above it. The consensus is that autoscopic hallucinations and, especially, out of body experiences, most commonly involve disturbance of the right temporoparietal or right parieto-occipital junctions.⁸⁰ A related condition, conventionally referred to as heautoscopy, in which the subject confronts a copy of himself at a distance (thought by some to be the origin of the concept of the *Doppelgänger*, though this is a technically different phenomenon) frequently involves the left temporoparietal junction; although according to the most extensive review of the literature to date, heautoscopy shows no hemispheric bias.⁸¹ The tendency for autoscopy to depend on right hemisphere lesions, however, remains robust.

Phantom limb

Here we are not talking about the phantom limb experienced by a person who has had a limb amputated, but the spontaneous generation of a phantom extra limb or limbs following brain injury. Of all reported cases in which lateralised pathology was determined, all but two involved the right hemisphere.

There are a number of early case reports. In 1930 Hans Ehrenwald described a patient who, following a right hemisphere stroke with left hemiplegia, said that he had a ‘nestful’ of hands in his bed.⁸² In 1954, Weinstein and colleagues reviewed a number of other cases from the ’20s and ’30s: a man with a left hemiplegia who, for several months, expressed the belief that he had two left hands, three heads and six feet; a patient who claimed he had two left ears; another with a left hemiplegia who maintained he had two left hands; and a detailed study of six cases of duplication of body parts in patients having left hemiplegia.⁸³ They also reported four cases of their own: a woman with a left-sided paralysis who had an extra hand and part of an arm on the left side; a soldier with left-sided weakness, who had an extra pair of legs coming off sideways at his hips; a young man with left-sided signs (and requiring drainage of the right lateral ventricle), who had between three and six heads at different times, and up to five bodies; and a fourth case, with bilateral brain damage and a right hemiplegia, who had four eyes, two heads, two bodies, four arms and four legs. Hécaen and Ajuriaguerra reported four further cases from the literature and two of their own: two were due to right hemisphere pathology, one due to left, and three are unspecified.⁸⁴ More recently four subjects have been reported having developed an extra arm: one after right basal ganglia stroke,⁸⁵ one after right frontomesial stroke,⁸⁶ one after right thalamocapsular stroke,⁸⁷ and one after a right middle cerebral artery haemorrhage.⁸⁸ One patient reported three hands, and sometimes three legs, after a lesion involving the right frontal lobe and the corpus callosum.⁸⁹ Another reported up to five extra arms after a right hemisphere stroke involving both the basal ganglia and the right temporoparietal cortex;⁹⁰ and another had at times up to six supernumerary phantom limbs after a right middle cerebral artery infarct: ‘the patient’s adamant and delusional conviction of their reality caused him considerable distress’.⁹¹ Following a right hemisphere stroke, the painter Otto Dix twice painted a hand with six fingers.

There is one case reported of an extra arm after left pontine haemorrhage.⁹²

Misoplegia

Misoplegia is not a delusion, strictly speaking, though ‘frankly psychotic types of thinking and behaviour may develop’.⁹³ It is a curious state of affairs in which the subject takes against a body part, and vilifies it verbally, hits it and harms it, and generally is not willing to be its friend. This happens most usually after right hemisphere damage, often to the inferior parietal lobule, and is part of the general hollowing out and loss of emotional depth that is associated with such damage, as well as the left hemisphere’s distaste for everything to do with the body (in addition to all we know about the relative distance from embodiment in the left hemisphere compared with the right, we know that disgust in various modalities – ie, from different senses – is associated with the left insula).⁹⁴ Sometimes, in right hemisphere damage, disgust can be targeted at an object simply because it lies in the left visual field.⁹⁵

Misoplegia is usually directed against a left-sided limb.⁹⁶ We might think ‘well, it is understandable that one gets upset with a limb that is literally not pulling its weight’. But this doesn’t seem to happen often against a right-sided limb, and the phenomenon does not, in any case, lie within the bounds of rationality. For example, although the term ‘misoplegia’ (literally, ‘hatred of a stroke’) suggests at least a degree of paralysis in the targeted limb, there is a fascinating case study that involves a limb that was doing a fine job – apart from being on the left side of the body, that is.⁹⁷ This involved a 79 year-old woman with a somewhat shorter left leg since childhood, who had all her life been fully mobile and active in sports that she enjoyed. Suddenly she started to curse and swear at the left leg and call it her enemy, though apparently it was functioning normally: there was an ‘absence, in our patient, of hemiplegia, or even of any marked sensory or motor impairments’. A few weeks after this started she was admitted to hospital with a right hemisphere tumour.

Initially, she just hit the leg and wished it were dead. After a while she took up alternately caressing and beating it. After the operation, signs of anosognosia were observed. For instance, despite the fact that, following the operation, she was confined to a wheelchair, she claimed that she could run.

Xenomelia

Most peculiar of all is a related condition: xenomelia (also known as dysmelia or apotemnophilia), in which the subject fervently seeks amputation of a perfectly healthy limb. It is associated with right hemisphere (usually parietal) disorders, and the target is usually a left-sided limb: ‘the predominantly right-sided cortical abnormalities are in line with a strong bias for left-sided limbs as the target of the amputation desire.’⁹⁸ Even when the target is a right-sided limb, however, the pathology is in the right hemisphere. Nonetheless, one case, which is not strictly xenomelia, but similar to it, involved a young man with a left temporoparietal injury who nonetheless requested surgery to remove his left, normally functioning, eye.⁹⁹

Koro and dhat

Koro is a ‘culture-bound’ syndrome, found principally in the Far East, but also sometimes in Africa and Europe, in which in men there is an irrational and overwhelming belief that their genitalia are retracting and will disappear, often coupled with an intense fear that death will occur once the retraction is complete. It has something in common with the syndrome known as *dhat*, a condition reportedly seen only in India, in which the belief that semen is being discharged in the urine is coupled with a religiously based belief that a vital life fluid is being drained from the body. Both overlap to some extent with Cotard’s syndrome, in that all three express a sense of devitalisation. The only evidence about lateralisation to date depends on two studies relating to *koro*, suggesting a possible connexion with right hemisphere dysfunction.¹⁰⁰ There is no suggestion that either *koro* or *dhat* could be related to left hemisphere dysfunction. But the evidence is clearly too scanty to permit any firm conclusions to be drawn.

PESSIMISM, OPTIMISM AND REALISM

The commonest causes of delusions over all are the illnesses of bipolar disorder (formerly, manic-depressive psychosis) and schizophrenia. I have so far left them to one side because they are not usually (though either can be) the result of overt brain lesions whose lateralisation can be assessed. However, the distinction between ‘functional’ psychoses, which were once thought not to involve significant brain abnormalities, and ‘organic’ psychoses, which clearly do, is misleading if taken literally. In Chapter 9 I will examine further the extent to which schizophrenia appears to involve right hemisphere dysfunction.

Insight into illness

On the topic of insight – awareness of one’s illness – if you have come to suspect that this was not the left hemisphere’s strong suit, you would be right. Such lack of insight is after all a form of anosognosia (denial of illness). Insight is very largely right hemisphere-dependent.¹⁰¹ Insight increases when right frontal and parietal lobe function improves, and deteriorates when it deteriorates.¹⁰² I found that a personnel officer with right frontal deficits had no insight into his incapacity to carry out his former work; but when asked what he would advise a colleague in his position to do, he readily agreed that such a person should not be at work. Such ‘third person’ scenarios are often successful where there is no insight into the self.¹⁰³

Although relatively speaking the right hemisphere takes a more pessimistic view of the self, it is also more realistic about it.¹⁰⁴ After all, it is the one with insight. There is a large literature on this topic, in which there are different views, but a fair summary is that depression has repeatedly been shown to be associated with greater realism – provided the depression is not too severe. A degree of depression increases insight into illness, which makes sense, since it is associated with relative dominance of the right frontal cortex. Even subjects with schizophrenia show insight into their illness proportionate to their depressive symptoms.¹⁰⁵ The evidence is

that this is not because insight makes you depressed, but because, up to a point, being depressed gives you insight.¹⁰⁶

In understanding one's role in bringing about a certain outcome, depressives are more 'in touch' with reality even than normal subjects: depressive subjects were remarkably accurate, whereas normal subjects overestimated their role in bringing about wished for results, and underestimated their role in bringing about unwished for results.¹⁰⁷ This must apply, however, to milder degrees of depression only, since one of the aspects of psychotic depression is the adoption of responsibility for events with which one has had nothing to do.

One might think that, if one of the consequences of right hemisphere stroke is that one is unwarrantedly optimistic, one of the consequences of left hemisphere stroke might be unwarranted pessimism, or even depression. However, the relationship between the right hemisphere and depression is complex: the evidence is that depression can be caused by either a *left frontal* dysfunction or a *right posterior* dysfunction.¹⁰⁸ As explained, the frontal cortex of either hemisphere is in a reciprocal equilibrium with the opposite frontal cortex, and also with its own posterior cortex; thus either left frontal dysfunction or right posterior dysfunction leads to a prepotency of the right frontal cortex. Although an early and influential study suggested that depression was globally commoner after left hemisphere stroke than after right hemisphere stroke,¹⁰⁹ the emerging picture from more recent research does not support this. A meta-analysis published in *The Lancet* in 2000 found that when data from 34 primary studies were pooled, lesion location was not associated with depression, though there was a relatively weak association with left frontal stroke, which is in keeping with a common sense view, since it is commonly associated with losing speech and use of the right hand, whereas right hemisphere stroke is associated with loss of insight into one's deficits.¹¹⁰ A systematic review of the literature in 2004 found no overall difference;¹¹¹ a more recent (2013) comparison of depression rates in left hemisphere and right hemisphere stroke also found no difference;¹¹² and the most recent and extensive systematic review (2015) of the literature 'offered no support for the hypothesis that lesion of the left hemisphere was associated with an increased risk of depression after stroke'. Indeed it found, rather counterintuitively, an association between *right* hemisphere stroke and

depression in the subacute post-stroke phase.¹¹³ A systematic review of apathy following stroke found no difference between the hemispheres, either.¹¹⁴ A Korean retrospective review of 226 sets of case notes did find that depression was less common after right hemisphere stroke, a finding which they attributed to the high level of anosognosia (unawareness of one's deficits). They concluded, however: 'the association between the site of the stroke lesion and the likelihood of the development of depression remains controversial'.¹¹⁵ The conclusion would appear to be that there is no straightforward relationship between laterality of stroke and developing depression.¹¹⁶

Clearly, there is a kind and degree of depression in which realism is lost. In this state it is often not so much negative affect that is encountered as loss of affect altogether. This, too,

appears to be associated with *right*, not left, hemisphere *deficits*. The greatest difference, both quantitatively and in terms of statistical significance, when comparing psychotic with non-psychotic depressed patients, was that those with psychotic symptoms showed marked *hypoperfusion* in the right inferior frontal cortex, with the focus being in the insula.¹¹⁷ Equally, subjects with psychotic depression may show *reduced* electrophysiological activity in the right frontal area.¹¹⁸ We know from everything else we have looked at that this region of the right hemisphere is of central importance for reality testing.

Both depression and time perception are right hemisphere mediated. One interesting aspect of depressive realism is that mild depression makes people better at judging the duration of time.¹¹⁹ Psychotic depression, however, clearly impairs accuracy of time perception, which seems to pass very slowly.

The right hemisphere is more in touch with how it stands in relation to the world at large, less grandiose, more self-aware, than the left hemisphere.¹²⁰ The left hemisphere, as you may well be able to predict by now, has higher self-esteem than the right.¹²¹ It is unreasonably optimistic, and it lacks insight into its own limitations.¹²² The left hemisphere latches onto positive information and shifts one's attention towards it, ignoring real

risks.¹²³ One of the more interesting aspects of this phenomenon has, once again, to do with the left hemisphere's deviant sense of responsibility. In an experiment designed to test how the left hemisphere interprets causation, information fed to the left hemisphere resulted in individuals attributing 'their successes to internal, stable and global causes, while failures were blamed on external, unstable and specific causes'.¹²⁴ In simple terms, it takes the kudos when things go well, and denies responsibility when they do not.

Right frontal damage, especially in the region of the inferior frontal gyrus, can cause fatuous optimism.¹²⁵ Using transcranial magnetic stimulation to *suppress* the right inferior frontal gyrus caused healthy participants to become abnormally optimistic about what would happen in the future, compared with their normal state.¹²⁶ In keeping with this, *facilitating* the right hemisphere reduced unreasonable optimism.¹²⁷

In a rather nice piece of research, neurologists have established a connexion between the 'smiley' emoticon and right frontal failure. The subject is asked to copy, or draw from memory, the Rey-Osterrieth figure (a standard test of visuo-spatial function, memory and attention).

Fig. 13. The Rey-Osterrieth figure

A neurological team noticed that a woman with a right frontal tumour, who was, in line with expectation, slightly manic, had a normal neuropsychological profile apart from the fact that she converted the element which consists of a circle containing three dots into a 'smiley' face,

‘like the fashion logo’ (in 1994 the smiley had not yet entered into daily messages):

Fig. 14. The ‘smiley’ sign in right anterior dysfunction (from Regard & Landis 1994)

They then had the idea of studying all the patients who, on recalling the figure, produced a ‘smiley’, to see if there was an increased likelihood of damage to the right hemisphere. Only very few, 37 out of the 2,400 patients referred for impaired cerebral function, produced a ‘smiley’ – about 1.5%, so it was definitely not a common perceptual error. But a highly significant number of those who did, had right hemisphere lesions, particularly in the right frontal region. No depressed patient produced a face with a downturned mouth, only a ‘smiley’ was ever produced; and in 83% of those cases there were signs of the patient being manic or hypomanic (that is to say, close to being manic), the commonest brain correlation being with right frontal deficits. The researchers concluded that ‘the occurrence of a “smiley” in the Rey complex figure is a rare, but reliable sign of functional impairment or structural damage to the right anterior brain’.¹²⁸

Whether we are well or ill, our left hemisphere is unaware of our shortcomings.¹²⁹ Feedback about performance is less effective in subjects with right hemisphere lesions, and they tend to underestimate their errors.¹³⁰ To quote Nikki Marinsek and colleagues, ‘*only* patients with right hemisphere brain damage continued to overestimate their ability to perform a task after they had *just failed* to perform the task in question [emphasis in original]’.¹³¹ And as Jaak Panksepp put it, the left hemisphere ‘appears

predisposed to repress negative emotions, and even *chooses* to confabulate'.¹³²

Intriguingly, there is an inverse problem for those with left hemisphere damage. Whereas the left hemisphere-intact patient underestimates the difficulty of a task and often performs badly, the right hemisphere-intact patient overestimates the difficulty of the task and often performs well. Though scoring highly on tests of working memory, selective attention and task switching – often higher than the left hemisphere-intact group – right hemisphere-intact subjects found themselves unable to tackle a problem because they were looking for something complex, and overlooked the easy solution:

After a successful solution, if patients were asked for the reason of their initial reluctances, a typical answer was that at the beginning his/her first impression was that one had to find something complex and previously unknown which could not be immediately clear from the situation. Therefore, a straightforward solution was ignored.¹³³

One patient said: 'I thought this would be too easy for a solution and that you gave me a more complex task.' Even more fascinating is that, according to Boris Velichkovsky, who has made a detailed study of patients with lesions in the left inferior parietal lobe, 'their problem lies in a general attitude towards task situations as *a priori unique* ... requiring tough mental efforts and sophisticated strategies of problem solving.'¹³⁴ This fits with the observation that, across a range of functions, while things are running routinely, the left hemisphere deals with them; but when they are exceptional – 'unique' or 'complex' – the right hemisphere is brought in to deal with the situation. It's as if the right hemisphere assumes that, if it is being drawn into involvement in the task, the problem is tough and unusual. The researchers found that, after an initial delay, patients 'suddenly arrived at the solution fast and correctly'. They call it 'difficulty of entrance in the task', and contrast it with a common problem after right hemisphere injury in particular, in which, by contrast, impulsivity, and instability of emotion and attention dominate the picture.

I have explained earlier why the left hemisphere is also unreliable in daily life: it has a tendency to jump to conclusions, to become entrenched,

to be unwilling to see other points of view and, frankly, to make stuff up, if it needs to, in order to maintain its point of view. And it has a desperate need for certainty. According to Marinsek and colleagues,

The left hemisphere appears to detest uncertainty; it creates explanations and fills in gaps of information in order to build a cohesive story and extinguish doubt.¹³⁵

Confabulation could be explained away as merely a confused response to a failure of memory, but it is more than that. Even when it remembers well, the left hemisphere exhibits a strong tendency to confabulate.¹³⁶ It may be said that the weird and wonderful delusions we have looked at are remote from our everyday experience. But their implications are not. Even in the normal situation, the left hemisphere is unreliable. Not only are subclinical delusional beliefs directly tied to left hemisphere activation in *normal participants* – not just psychiatric patients – but self-reference is related to the same left-sided area of brain activation, particularly delusional self-reference, the basis for paranoia.¹³⁷

FALSE 'MEMORIES' AND CONFABULATION

According to Michael Gazzaniga,

when presented with new information, people usually remember much of what they experience. When questioned, they also usually claim to remember things that were not truly part of the experience. If split-brain patients are given such tests, the left hemisphere generates many false reports. But the right brain does not; it provides a much more veridical account.¹³⁸

The psychological literature sometimes confuses two completely different kinds of phenomena under the heading 'false memories' (I am leaving to one side the phenomenon of 'false memory syndrome', an entirely different matter – though there, as in confabulation, a failure of right hemisphere inhibitory control has been posited).¹³⁹ On the one hand is a completely fabricated, experiential, or autobiographical, memory – 'I was in Holland yesterday' or 'I had three sisters', when, as an only child, you were yesterday in Birmingham. On the other is an increased willingness to say that a word or a picture now experimentally displayed to you was also present in a random display shown to you previously. The first is spontaneous, severe, and quasi-delusional, and is definitely commoner after right hemisphere damage. The second, often called 'false recognition', can be detected only experimentally, is mild, non-delusional and simply over-inclusive; and it may occur after damage to either hemisphere.

Having said that, a large number of studies show that false recognition of list items does in fact increase after right hemisphere lesions. This is principally because the left hemisphere is less interested in uniqueness, more in the category, and so may lump two similar items together.¹⁴⁰ For example, the right fusiform gyrus (an occipitotemporal region, important in face recognition) responds strongly to the specifics of an image, such as its size, colour, shape, or orientation; it habituates quickly if shown a picture of the same particular kitten, but not if shown a different one: 'Great! it's new, unique material!' Meanwhile the left fusiform gyrus habituates even when a completely different kitten is shown: 'Same old, same old ...'¹⁴¹ Remember

that to the right hemisphere everything is relatively new, whereas to the left hemisphere everything is already somewhat familiar. This may be one reason, at least, why people with right hemisphere deficit conditions such as ADHD (attention deficit and hyperactivity disorder) are easily bored;¹⁴² maybe even why we as a society are becoming so much in need of stimulation (there are of course others).

Patients with right hemisphere lesions, particularly in frontal regions, have been shown to produce more false memories than controls in studies using words,¹⁴³ faces,¹⁴⁴ and pictures.¹⁴⁵ Similarly a right hemispherectomy patient 'failed to recognize cards he had seen before, and then again he believed to have seen cards already which were shown to him for the first time'.¹⁴⁶ In a structural neuroimaging study healthy participants who generated the highest levels of false memories also possessed the lowest densities of grey matter in the same region of interest, specifically the right frontal gyrus.¹⁴⁷ In fact, according to Braun and colleagues, it has repeatedly been observed

that right hemisphere-lesioned patients make relatively more commission errors (incorrect recall, i.e., false recognitions) on memory tasks than do left hemisphere-lesioned patients. This literature has been almost completely ignored in the mainstream memory neuroscience literature.¹⁴⁸

The right hemisphere is more cautious, so that lesions in the right hemisphere make patients liable to 'recognise' what is not in fact familiar, while left hemisphere-lesioned patients tend to err in the opposite direction.¹⁴⁹

Normal subjects are better able to remember imagery in the left visual field, served by the right hemisphere.¹⁵⁰ Studies in two split-brain subjects, JW and VP, suggest that recognition in the right hemisphere is more veridical.¹⁵¹ Evidence suggests that memory in general, for anything other than verbal material, is more impaired after right hemisphere stroke than left.¹⁵²

Of course, the ideal situation is for the hemispheres to co-operate. However, even there, in the intact normal brain, the critical factor is what the right hemisphere communicates to the left; input from the left to the

right does not appear to improve performance significantly.¹⁵³ That, too, is supported by the findings from brain-damaged patients:

We found that patients with left hemisphere lesions were not impaired compared to controls in any of the tasks. Patients with right hemisphere lesions were not significantly impaired in memory for visual words, but were impaired in recognition of object pictures and sounds.¹⁵⁴

In other words, the left hemisphere made no difference whatever the type of study, but when it came to *non-linguistic* tasks, the input of the right hemisphere was the critical factor. And in another study right hemisphere-damaged patients performed worse on the recognition tests than either normal controls or left hemisphere-damaged patients, across all categories of stimuli.¹⁵⁵ Giving the left hemisphere more time does not help, but actually increases its error rate, while more time makes no difference to the performance of the right hemisphere.¹⁵⁶

The left hemisphere is more restricted, in terms of its capacity to make associations, than the right hemisphere.¹⁵⁷ Thus the same tendency that makes the right hemisphere capable of casting its perceptual and cognitive net wider than the left, making both more, and more remote, connexions than the left, must be expected at times to lead to false positives in recognition tasks.¹⁵⁸

One study sensibly concludes that ‘inter-hemispheric co-operation models may be necessary to fully account for false emotional memories’ (and their avoidance).¹⁵⁹ And another such study, entitled ‘How do our brain hemispheres co-operate to avoid false memories?’, concludes that, as regards false recognition tasks, ‘even though relatively large in number, these studies failed to reveal a superiority of one hemisphere’ (acting on its own).¹⁶⁰

If however, we return to the matter of false, autobiographical memories – our first category – there is a mass of evidence that the right hemisphere is more important for veridical memory.¹⁶¹ There is greater right prefrontal cortical activation during recognition of personal autobiographical memory than of other kinds;¹⁶² loss of autobiographical memories, particularly the ability to re-experience them as elements of one’s personal past, is

associated with damage to the right inferior frontal cortex, and to the long white matter tract, the uncinate fasciculus, that connects it to the anterior temporal lobe.¹⁶³ But, in any case, the left hemisphere, Gazzaniga's story spinner, seems not to be particularly interested in truth, as we have already repeatedly seen.¹⁶⁴

Insight – or lack of it – into one's own motivations betrays a similar hemisphere difference. There is a huge discrepancy, showing little overlap, between one's explicitly expressed motivations and those revealed implicitly by psychological tests making use of non-verbal imagery, such as the thematic apperception test (TAT), in which subjects are asked to construct a narrative to explain pictures of human situations, thereby revealing otherwise unexpressed motivations.¹⁶⁵ Our implicit motives are derived from deep, unconscious, affect-laden experience, whereas motives we attribute to ourselves are cognitively elaborated constructs.¹⁶⁶ A person whose TAT stories are full of imagery related to having impact on others through all sorts of means – a power-motivated person, in other words – may describe himself as not interested in power at all. Of course, sometimes we are guided by our own explicit self-ascriptions and goals, and at others by our implicit motives, so both are relevant to understanding how we behave. According to David McClelland, who developed the influential Achievement Motivation Theory, implicit motives are a right-hemispheric phenomenon and explicit motives are left-hemispheric.¹⁶⁷

All in all, the left hemisphere just is not reliable about the self. And since, in a sense, the self is all we know directly, that's got to be a handicap. 'Humankind', wrote T.S. Eliot, 'cannot bear very much reality'.¹⁶⁸ In as far as this reflects the way of being of the left hemisphere, he was certainly right.

MAGICAL THINKING

Finally, let's turn to magical thinking, since it has been linked by some researchers with the right, rather than left, hemisphere. Magical thinking is defined as 'belief in forms of causation that by convention are invalid', a phenomenon which exists in all of us to some extent. Is it, though, in fact associated with the right hemisphere? Since it involves making more remote connexions, it would make sense if it did.¹⁶⁹ Magical thinking is associated with creativity;¹⁷⁰ and, for similar reasons, creativity is highly right hemisphere-dependent (see Chapter 8 below).

But the laterality of magical thinking is not clear. It may be left hemisphere-related: for example, inhibition of the left lateral temporal area produced a significantly reduced tendency to report apparently 'meaningful' events.¹⁷¹ Direct studies of the laterality of magical ideation have proved negative or inconclusive.¹⁷²

In more extreme form it is part of the picture of schizotypy¹⁷³ – a personality type that has some features in common with schizophrenia, but without (except for brief episodes) loss of contact with reality. Schizotypal individuals are often labelled 'odd' or eccentric': they typically exhibit peculiar behaviour, speech mannerisms, constricted affect, have few or no close friends, find trusting and socialising problematic, and are unduly suspicious – none of which suggests right hemisphere enhancement.

You might expect levels of magical thinking, though not schizotypy, to be higher among religious subjects, and this is the case in males (though not females) that have been studied; yet there is no association between religion, in either sex, and the other factors that constitute schizotypy.¹⁷⁴ There are also higher levels of magical thinking in experienced meditators and mindfulness practitioners, but again no relation with other measures of schizotypy: for example, meditators showed *lower* levels of suspiciousness and social anxiety than non-meditators.¹⁷⁵

And, if magical thinking is indeed bound up with schizotypy, schizotypy itself shows no clear lateralisation. To quote one contemporary study,

Unfortunately the previous literature on links between schizotypy and hemispheric asymmetry is inconsistent, with some research indicating that elevated schizotypy is associated with relative right over left hemisphere shifts, left over right hemisphere shifts, bilateral impairments, or with no hemispheric differences at all ...

[176](#)

The authors of this study conclude that any link between schizotypy and laterality is either so subtle that it is incapable of being assessed by traditional methodologies, or does not exist – or is mediated by other factors altogether. And if schizotypy were really associated with the right hemisphere, it would remain to be explained why schizotypals characteristically display not only social and emotional impairments, but deficits in sustained attention,[177](#) since this strongly suggests diminished, rather than enhanced, right hemisphere activity.

All of which, along with the formulation of magical thinking as ‘belief in forms of causation that by convention are invalid’, leads one to wonder how valid the whole construct of magical thinking itself really is. Is it just the modern Western stigmatising of a normal and useful thinking style present in all other cultures? Animist intuitions, which we would conventionally consider ‘magical’ thinking, are deep in the psyche of, for example, the modern Japanese, whatever their religion, and are not related to educational level.[178](#) Studies of magical thinking in the context of ethnicity are few, but one carried out in New Zealand suggests that magical thinking is commoner among Maoris than among Western settlers.[179](#) And there is more in common than one might at first think between the average Westerner’s acceptance of the efficacy of aspirin and the African villager’s acceptance of a spell from the witch doctor: neither understands, or even asks for, a causal explanation, but accepts treatment on the basis of authority and past experience. As anthropologist and philosopher Robin Horton puts it, ‘the layman’s grounds for accepting the models propounded by the scientist are often no different from the young African villager’s ground for accepting the models propounded by one of his elders.’ [180](#)

However, even in the West, there is a significant difference between what we say we believe (which is what rating scales assess) and what we *actually* believe when push comes to shove. For example, in one study

British adults were shown an impossible event – the unexpected destruction of an object in an apparently empty box – for which both a bogus scientific explanation and a bogus magical explanation were given. Unsurprisingly, in their verbalised judgments, the subjects showed ‘a higher degree of credulity toward scientific explanations than toward magical explanations’. However, in another situation, where the stakes were high enough, British adults endorsed scientific and magical explanations to an equal extent. ‘This result’, the experimenters conclude,

was in support of the main hypothesis: scientific education eliminates non-institutionalised magical beliefs from adults’ verbal thinking, yet in non-verbal behavioural responses, adults’ non-institutionalised magical beliefs are still present.¹⁸¹

The experiment was then repeated in Mexico. In pre-test conditions, Western participants showed themselves much less ready to believe in magic than their Mexican counterparts. But ‘in their non-verbal behaviour or reactions in the high-risk condition, Mexican and British participants endorsed beliefs in the efficacy of the magic spell to an approximately equal extent.’¹⁸² And they conclude (the italics are theirs):

*When the risk was high, non-institutionalised magical beliefs ascended to the level of consciousness and British participants showed credulity toward magical beliefs to the same extent as did Mexican participants.*¹⁸³

In another experiment, British graduates and undergraduates, ‘all informed disbelievers in magic’, were asked to consider an imaginary scenario in which a witch approached them on an empty street and offered to put a magic spell on their future lives.¹⁸⁴ Revealingly, the proposal induced different reactions depending on whether the proffered spell was good or bad. Whereas 50% of participants declined the good spell, all participants declined the bad spell:

contrary to their self-proclaimed disbelief in magic, in their justifications of why they had rejected the bad spell, the participants

admitted that the bad spell might actually affect their future lives in a magical way ... [U]nder certain conditions, children and adults who initially deny having magical beliefs will openly and willingly acknowledge that they believe in magic, and the number of such participants will be close to 100%.¹⁸⁵

This finding has been replicated in other studies.¹⁸⁶ And in another experiment, this time not involving magic as such, but an irrational model of causation (a ‘belief in forms of causation that by convention are invalid’), Western participants were asked to drink from two glasses of water, both of which contained a small amount of sugar syrup only. The investigators assured participants that both were completely safe, but one was to be labelled ‘poisonous’. They even asked participants to select which label went with which glass, proving that the labels were strictly meaningless. Even so, participants were hesitant to drink from the glass once it was labelled ‘poisonous’. They were even reluctant to drink from a glass labelled ‘not poisonous’ – the very presence of the word ‘poison’ on the label seemed enough.¹⁸⁷ In yet another study, again Western participants were reluctant to wear ‘Hitler’s sweater’.¹⁸⁸ And educated, non-superstitious Western subjects can easily be induced to believe that they have somehow influenced another person’s decision merely by concentrating on it.¹⁸⁹

So is magical ideation, in fact, normal? Scores on the Magical Ideation Scale up to nearly 14/20 in men, and up to nearly 16/20 in women, would lie within one standard deviation of the mean (that is to say, would still only capture 68% of normal subjects), a score that has been normalised on over 1,500 Western college students. Perhaps magical ideation is functional, rather than dysfunctional. According to Eugene Subbotsky, his studies ‘confirmed the assumption that magical thinking is relevant for learning and education: in some conditions, viewing magical effects appears to enhance creative thinking, helps memorize certain aspects of the display, and helps differentiate between fantasy and reality.’¹⁹⁰ That claim seems a little ambitious to me, but whether that is so or not, ‘magical ideation’ is by definition not in itself delusional, though it may be on a continuum with delusion. It simply suggests a greater willingness to consider connexions, some of which are no doubt non-existent, but some of which may simply

not be recognised in the current Western standard model. As science advances, it successively reveals that animals, birds and fishes are capable of far more spectacular feats of cognition than we were prepared only a few years ago to allow, including some that we cannot as yet explain. Some physicists are now prepared to accept a number of realities that are contrary to what used to be conventionally accepted, such as apparent action at a distance, the apparent influence of consciousness on the behaviour of matter, and the possibility of holographic existence. Biology, too, teaches us that the mind can have effects on matter (eg, the placebo effect), and that information acquired in one lifetime can be transferred from one generation to the next (epigenetics), both of which used to be denied. Probably some of what we consider magical thinking will remain so; probably some will not. And that which is ultimately without foundation may hardly be disadvantageous, simply being an exaggeration of a cautionary principle that makes sense in terms of survival: it's better to see tigers in leaf patterns where there aren't any, than to fail to spot tigers in leaf patterns where there are.

Magical thinking may not be pathological at all, except in extreme cases. It suggests to me an inverted U-shaped curve. Living at either extreme means being duped. Too little means you are not only unimaginative and uncreative, but at risk of failing to spot the obvious (the tiger that is there); too much means you are at risk of delusion (spotting the tiger that isn't). According to Peter Brugger, head of neuropsychology at University Hospital, Zurich, and probably the world's leading researcher into magical thinking, to be 'totally "unmagical" is very unhealthy', and reduces one's capacity to appreciate value and to take enjoyment in life.^{[191](#)}

JUDGMENTS FORMED ON INTUITION

Most PET imaging studies have shown predominantly right-sided orbitofrontal activation while involved in decision-making, such as assessing conflicting possibilities – eg, frequent small rewards versus occasional large rewards – on a risk task.¹⁹² Lesion studies suggest that evaluating decisions depends, in general, on the right ventromedial prefrontal cortex (VMPFC).¹⁹³ In a comparison between normal subjects and addicts in a functional MRI task, healthy controls were found to have significant right-sided activation (in the lateral orbitofrontal cortex, superior frontal gyrus, dorsolateral prefrontal cortex, inferior temporal gyrus, inferior parietal gyrus, lingual gyrus, occipital cortex and cerebellum): but the addicts, whose decision-making was chaotic and irrational, showed a reverse pattern:

During decision-making, control participants showed relatively greater activation in the right dorsolateral prefrontal cortex, whereas participants engaged in current or previous drug use showed relatively greater activation in the left orbitofrontal cortex.¹⁹⁴

There is, however, evidence from three studies that I am aware of that this may apply only to men, and that in women, it is the *left*, not the right, VMPFC that is more important in decision-making.¹⁹⁵ If this turns out to be more widely replicated, it joins a similar anomaly regarding sex-specific lateralisation in the amygdala, where activity in relation to emotionally charged memories is once again right-lateralised in men, left-lateralised in women.¹⁹⁶ To an extent the finding that the VMPFC and the amygdala vary *together* makes sense, in that the VMPFC is involved, amongst other things, in dealing with affect-laden memories, as is the amygdala.

An aside on differences between sexes

As to the significance of such (sexually divergent) findings, there are very few clues at this stage. One possible theory is that while their effect

may lead to behavioural differences in some instances, they might just as well be designed to prevent such differences (when, for instance, they would be maladaptive), by compensating for sex differences in other physiological conditions, such as endocrine function.¹⁹⁷ If, for example, the right frontal cortex is so crucial in females for underwriting the empathic relationship with the infant, it may not be possible for the same area to make risk decisions, which, from an evolutionary psychology point of view, are more the domain of the male. But we would need more research into what other sex-specific aspects of lateralisation exist to have a basis for a useful global conjecture.

What seems to be clear, however, is that striking sex differences in functional asymmetry do exist, and they have been ascribed, at least in part, to the action of sex hormones, especially testosterone.¹⁹⁸ Many individual studies have found greater functional asymmetry in men than women,¹⁹⁹ and all five reviews of the literature of which I am aware reach the same conclusion,²⁰⁰ though there are occasional contrary findings.²⁰¹ There are a number of corollaries of this. Men are more likely to display verbal deficits after left hemisphere lesions and non-verbal deficits after right hemisphere lesions, whereas the deficits are less predictable for women.²⁰² Additionally male brains exhibit greater *intra*hemispheric, and females greater *inter*hemispheric, structural connectivity.²⁰³ What these findings together suggest is that the hemispheres are more specialised in the male than the female brain.²⁰⁴ This could be expected to lead to complementary patterns of strengths and weaknesses.

In normal adults, sex differences in functional cerebral asymmetries have been reported in wide range of areas, including decision-making, as above, but extending to areas such as language, working memory, spatial orientation, spatial attention, face perception, verbal and musical creativity tasks, emotional 'processing' and appreciation of beauty.²⁰⁵ Except in the case of language, males have generally been found in every one of these areas to be more reliant on the right hemisphere than females.

Doreen Kimura proposed that males prefer to employ right hemisphere, non-verbal systems whereas females prefer to employ left hemisphere, verbal systems.²⁰⁶ Women tend to use a more verbal strategy than men in non-verbal tasks.²⁰⁷ They also employ a different cognitive strategy from men in navigation tasks, relying predominantly on landmark [local or

‘egocentric’] information, ‘whereas men used both landmark and geometric [global or ‘allocentric’] information’.²⁰⁸ In general, as we have seen, we transfer more information, and more swiftly, from the right hemisphere to the left, but this asymmetry seems to be less pronounced in women, who show more symmetrical interhemispheric transfer times than men.²⁰⁹

According to Belinda Pletzer, one of the leading researchers in the area, many lines of evidence show that males process more globally, females more locally: there is ‘a stronger focus on the global level (holistic processing) in men and a stronger focus on the local level (decomposed processing) in women’.²¹⁰ The first is more right hemisphere-dependent and the second more left hemisphere-dependent. Men show greater right hemisphere activation in tasks assessing global attention.²¹¹ In women, global choices are slower than local choices, whereas in men they are faster. Testosterone is positively related, and progesterone negatively related, to the use of global strategies.²¹² Oral contraceptive users show enhanced global advantage compared to women whose menstrual cycle is natural.²¹³ It has repeatedly been demonstrated that men tend to remember the gist of an emotional story more strongly than women, while women tend to remember the details of the same story more strongly than men.²¹⁴ A study by Deborah Waber and Jane Holmes asked girls and boys simply to copy the Rey-Osterrieth figure (see Fig. 13 above). They found that

at the youngest age, females reproduced more parts of the design (ie, scored higher on accuracy) than did males. This difference was accounted for by the presence, in the girls’ designs, of internal details absent in those of the boys. In addition, females drew more discrete parts than males, even when the total number of parts was statistically controlled. For males the external configuration of the design seemed to be more salient ...

They further found that, at age 11,

males drew their designs in long, sweeping, continuous lines, while females drew theirs part by part. At age 13, the stylistic difference between the sexes had once again disappeared ... The male superiority in spatial ability appears on three kinds of tests. The first

is spatial visualisation ... The second is perceptual disembedding ... The third is mazes ... These differences do not appear reliably until adolescence. The language abilities at which females show an advantage are clearly associated with left hemisphere function.²¹⁵

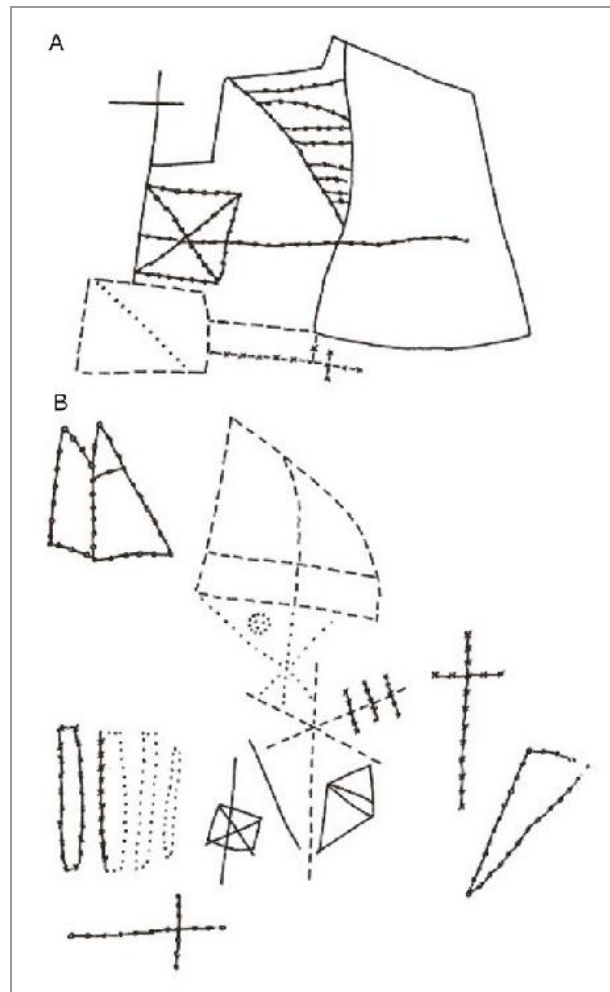

Fig. 15. Copies of the Rey- Osterrieth figure drawn by (A) a 5 year-old boy and (B) a 5 year-old girl. The different line styles are intended to give information about the order in which parts of the figure were drawn: see original for details (from Waber 1979)

In another study in children, 40 girls and 39 boys between the ages of four and 12 years undertook a perceptual judgment task. 'Boys were significantly more global in their perceptual judgments than girls at all ages. Younger children of both sexes were less global than older children. Results were consistent with developmental models that suggest an early left

hemisphere advantage for girls and a right hemisphere advantage for boys'.²¹⁶ And in a study of adult male and female composers, the compositions that received the highest ratings were by subjects that had smaller left hemisphere advantages in verbal processing, suggesting a greater reliance on the right hemisphere. However, though male composers across the board showed this smaller left hemisphere advantage compared with non-musicians, the opposite was the case with female composers taken as a whole, who showed greater left hemisphere advantage. This is in keeping with the fact that in male adults musical talent appears to be associated with high scores on spatial tests, whereas adult women show no such association.²¹⁷

I am sometimes asked whether one can say that the left hemisphere is in some sense 'male' and the right hemisphere 'female'. I know why the question is asked, but there can naturally be no such simple equation; and, as I pointed out at the beginning of *The Master and his Emissary*, if anything the evidence might be taken to point the other way. Quite apart from what I have just related, one needs to take into account a number of other facts that ought to give pause for thought. For example, though the right hemisphere is larger than the left, this effect seems to be more marked in males.²¹⁸ The surface area of the right hemisphere is also greater than that of the left, but the effect is greater in males.²¹⁹ It is testosterone that causes the right hemisphere to grow faster *in utero* in males than the left, actually inhibiting left hemisphere growth in order to produce resulting compensatory growth of the homologue regions in the right hemisphere.²²⁰ Higher levels of foetal testosterone cause rightward enlargement of a posterior part of the corpus callosum, the isthmus, which projects mainly to parietal and superior temporal areas.²²¹ The larger grey matter volumes found in the right temporoparietal junction and posterior superior temporal sulcus in males correlate positively with foetal testosterone levels.²²² Testosterone causes relative cortical thinning in the left hemisphere in males, and causes initially relative cortical thickening in the right hemisphere in females, though this effect in females is reversed later in development.²²³ Left hemisphere language-associated cortical regions are proportionally larger in the female brain.²²⁴ Prenatal testosterone causes left hemisphere lateralisation of language in girls and right hemisphere lateralisation of emotion recognition in boys.²²⁵ A left hemisphere focus for

speech functions matures earlier in females than males.²²⁶ While there are 20–30% more neurones in the male neocortex than the female neocortex overall, the difference is greater in the right hemisphere.²²⁷ Women have significantly larger neuronal somata in the left hemisphere than the right, which, it has been posited, relate to higher rates of right-handedness in females than males, and the female language advantage.²²⁸ And the two most reliable sex differences, neuropsychologically speaking, are that females in general have greater verbal facility and males better visuo-spatial skills, and that this is related to testosterone.²²⁹ Females do better academically where material is familiar and prepared.²³⁰ Finally, in rats, too, it has been found that the right cortex is thicker than the left in males, but the left thicker than the right in females.²³¹

The situation is undoubtedly complex.²³² There are differences between the effects of prenatal and adult levels of testosterone, metabolites of testosterone have differing actions, the same levels of testosterone in males and females have differing actions, and there is in general no simple dose-response curve.²³³ Meanwhile, the lesson we should learn is that all studies of brain structure and function should report results for males and females separately, and indeed, since sex hormones affect lateralisation of brain functioning, arguably differentiate women according to phase of the menstrual cycle and contraceptive use: ‘studies comparing men and women may fail to detect significant differences without controlling for hormonal contraceptive use’.²³⁴ We do not know how many important brain functional asymmetries have been missed by aggregated data cancelling out an otherwise significant effect.²³⁵ Where it is lateralised to different hemispheres in males and females, the most clearly lateralised function might potentially show no lateralisation whatever if equal numbers of men and women in a study are, as is often the case at present, grouped together.

THE ROLE OF REASONING IN FORMING JUDGMENTS

Reasoning is classically associated with the left hemisphere, but in reality most studies show that both hemispheres contribute to reasoning; and the part played by the right hemisphere is significant, as we shall see.²³⁶ Several studies report impairment in reasoning accuracy as a consequence of lesions in the left hemisphere,²³⁷ but others report impairments in reasoning following right hemisphere damage that are in reality more of a handicap. That's because they involve not just hypothetical logical problems, but inferring complex and ambivalent or implicit meaning, inferring what is going on in another person's mind and knowing how to understand the situation as a whole. As I have repeatedly emphasised, the old dichotomy – left hemisphere rational, right hemisphere emotional – is profoundly mistaken, on both counts; not to mention the fact that reason and emotion are never entirely separable. Knowing the limits to reason is essential to understanding. If not coupled with contextual, implicit and intuitive understanding (in none of which the left hemisphere excels), it can magnify error. As Sass and Pienkos point out: 'The most deluded patients with schizophrenia tend to be those whose thinking is more logical.'²³⁸ This is in line with Eugène Minkowski's insight that the problem in psychosis is not loss of reason, but its hypertrophy: 'The mad person is much less frequently "irrational" than is believed: perhaps, indeed, he is never irrational at all.'²³⁹ Here he was anticipated by G.K. Chesterton:

If you argue with a madman, it is extremely probable that you will get the worst of it; for in many ways his mind moves all the quicker for not being delayed by the things that go with good judgment ... He is the more logical for losing certain sane affections. Indeed, the common phrase for insanity is in this respect a misleading one. The madman is not the man who has lost his reason. The madman is the man who has lost everything except his reason.²⁴⁰

As Vinod Goel, one of the leading researchers in this field, rightly says, 'there is a long tradition in neuropsychology, backed by robust lesion data, suggesting left hemisphere dominance for reasoning processes'. Yet the

situation is not nearly as straightforward as this makes it sound, as he himself goes on to admit. For a start – and it is just an incidental, but nonetheless telling, observation – of the three journal papers that he cites in support of this remark, the first is a famous paper that argues, entirely plausibly, that the left hemisphere is an ‘interpreter’, that misuses reason to confabulate – makes things up – rather than admit it does not know what it is talking about, whereas the more tentative right hemisphere sticks to what it knows, and is closer to the truth.²⁴¹ The second paper demonstrates that the left hemisphere misuses reason by adopting a superficially ‘clever’ strategy that is actually irrational, if thought through properly, and gets the answer wrong, while the right hemisphere does the rationally superior thing and gets the answer right.²⁴² And the third paper, while not denying that the left hemisphere is importantly involved in the reasoning process, is concerned to make the point that the right hemisphere, in the end, by ‘an intelligent process akin to problem solving’, deduces from visual information the nature of the world better than the left. The paper’s author, Michael Corballis, another distinguished hemisphere researcher, postulates the existence of

a ‘right-hemisphere interpreter’ dedicated to constructing a representation of the visual world ... the right hemisphere can be conceived as more perceptually intelligent than the left ...[the left hemisphere] has traditionally been regarded as the ‘major’ or ‘dominant’ hemisphere, with the right hemisphere relegated to a minor, supporting role. This conceptualisation overlooks the fundamentally ambiguous nature of visual perception, and the profound ‘intelligence’ required to create a veridical representation of the world from the information provided by the retinal image.²⁴³

We have seen the stark evidence of this in this chapter.

Research into reasoning is complicated by many factors, not least being the various phenomena covered by the term and the many ways of trying to isolate them in an experimental design.²⁴⁴ I cannot pretend to be comprehensive here – that would be another book with another purpose, and I’d not be the best person to write it. But I will try to draw a number of

distinctions, from which, I believe, a new perspective on reason and intuition emerges, informed by understanding hemispheric differences.

Induction and deduction

One ancient distinction in reasoning processes is that between induction and deduction. Induction is, in a more immediate sense than deduction, about predicting the future, and is based on observing the ‘form’ so far: the sun rose every morning to date, so it will in all likelihood do so tomorrow. Induction relies on the familiar remaining unchanged. This kind of reasoning is particularly associated with the left hemisphere, which makes sense if we realise that the left hemisphere needs to be able to predict, since its main concern is a plan of action. It therefore, unsurprisingly, likes predictability, familiarity and certainty. With that in mind, one has to be aware that this kind of reasoning is nonetheless *intrinsically uncertain*; the result is that the tendency of the left hemisphere is to treat things as more certain than they are. This can give rise to a problem. It could lead you to believe, for example, that all swans are white, simply because you have never seen a black one. Nassim Nicholas Taleb famously wrote a book, entitled *The Black Swan*, about problems of this kind: in his view they led to the Western economic collapse of 2008.²⁴⁵ The Covid-19 crisis would be another example of something we had come to believe was vanishingly rare, but if it did happen would be devastating. So we chose to ignore the possibility until it was too late. The ultimate case is that of environmental destruction, and extinction of species: it’s seemed OK round here to date, so there isn’t a problem. It’s the right hemisphere that is on the alert; the left is too busy getting the next bonus.

Inductive reasoning is based on an assumption of the normal and expectable. And it involves brain areas that are used to recall general knowledge – a typical left hemisphere task.²⁴⁶

Inductive reasoning lies behind the so-called *Einstellung* effect. This is the tendency to get fixed in one’s method of approach, so that one fails to see other, better, ways of seeing a situation, or of tackling a problem. Once one has mastered a way of doing something that works well enough in one situation, one tends to carry on applying the same method to situations or problems in which it is inferior or inappropriate. It was most famously

demonstrated in a test devised by Abraham Luchins in 1942. He found that the tendency increased with age in adults, and was somewhat more marked in females than in males.²⁴⁷ It has since been found, as mentioned, to be less prominent in non-Westerners, who are more flexible in their thinking. Westerners ‘may never even consider that the problem could have multiple solutions, until explicitly told “Don’t be afraid to try new things” which clearly states the possibility of multiple solutions.’²⁴⁸

Deduction, by contrast, is seeing that something is *implied* by what one knows, and is latent or implicit in it – though not yet explicitly stated. To take another example from the fauna of Australia: if mammals are those that suckle their young, and the platypus suckles her young, the implication is that the platypus is a mammal, even if she has a beak and lays eggs. Deduction is about uncovering and integrating latent meaning so long as it makes sense, and rejecting it if it is discrepant – but not just because it is *unfamiliar*, or necessitates a recasting of one’s thinking. If such a recasting seems reasonable, an advance in understanding has been achieved.

Deduction is more persuasive than induction when deployed as an argument. For example, explaining that the mode of transmission of HIV makes it impossible to contract AIDS by casual contact (deduction) is more convincing than stating that no-one has yet caught AIDS from casual contact (induction).²⁴⁹

The right hemisphere plays a bigger part in deduction than induction, though in both the left hemisphere generally plays the leading role – with some important exceptions, to which we now turn.²⁵⁰

What do we know about the ways in which each hemisphere contributes to reasoning?

It has long been well-known that we do better at reasoning tasks when the logical conclusion is consistent with our beliefs about the world: when it is not, we make more mistakes.²⁵¹ This is because, when we reason about familiar situations, we automatically bring into play what in the jargon is called a heuristic, a ‘rule of thumb’ for that type of situation, based on experience, enabling a quick response. But when the situation is unfamiliar, we fall back on formal reasoning methods to solve the problem, which take more time. Where there is a conflict between our beliefs and the logical inference, we need to inhibit the dominant (‘quick and dirty’) response associated with our belief bias, and engage more formal reasoning processes.

In which of these situations do you imagine the right hemisphere plays more of a role? The first, ‘quick and dirty’ one, right?

Wrong. It is the *left* hemisphere that tends to reach hasty conclusions on the basis of what seems likely²⁵² – and it does well as long as the stimuli follow predictable patterns, less well when they do not.²⁵³ One of the most recently evolved areas of the brain, the right dorsolateral prefrontal cortex, plays an especially critical role in counterbalancing this tendency.²⁵⁴ This part of the brain has repeatedly been shown to be crucial to judgments where there are either conflicts between the facts being put forward and what we know from experience, or between what we know from experience and what reasoning suggests.²⁵⁵ Indeed, you could say that it acts somewhat as a wise judge would: taking into account all circumstances, and not being either swayed by bias or driven by untempered rationality. The mere presence of counterfactual statements is sufficient to engage this region of the right frontal cortex.²⁵⁶

There is a distinction to be drawn between two kinds of false conclusion: one drawn correctly but from false premisses, and one drawn incorrectly but from true premisses. An example of the first might be ‘the Sahara is freezing cold; there is much ice in the Sahara’; and of the second ‘the Sahara is hot and dry; there is much ice in the Sahara’. In the second type the conclusion is judged by both hemispheres to be false. However it is not so with the first type. An experiment by Deglin & Kinsbourne which I will describe in Chapter 10 demonstrates that the right hemisphere judges the conclusion in the first type to be false, as you might imagine; however, the left hemisphere judges the conclusion to be correct, since the logical structure is intact.²⁵⁷

Deciding when to go with logic and when to go with real-world experience activates the right hemisphere, since, when it is *inactive*, we answer the question ‘is this true?’ by reference to the internal logic of the system alone.²⁵⁸

I mentioned bias: if the right lateral prefrontal cortex is impaired, we are more swayed by our prior beliefs.²⁵⁹ One related difference between right and left prefrontal cortex activation is that the left dominates where belief bias points to the correct conclusion, and, by contrast, the right dominates where it does not.²⁶⁰ Belief bias is in fact generally associated with the left hemisphere, not with the right hemisphere.²⁶¹ In first detecting conflict

between our bias and the logic; in then inhibiting our ‘quick and dirty’ response; and finally in maintaining the subsequent chain of reason, it is the right, not the left, hemisphere that matters. And in fact one of the right hemisphere’s roles in logic seems to be the active searching out of counter-examples.²⁶² Perhaps, to the extent that rationalising is a function of the left hemisphere, Mercier and Sperber are right that rationality is not about seeking the truth – more about finding reasons that enable one to win an argument.

More generally, as I have tried to convey, it is the right hemisphere that helps us to get beyond our familiar simulacrum of the world, with its self-reinforcing tendency – what I have dubbed the hall of mirrors – to a more authentic, ‘in touch’, actuality. But it is not that the right hemisphere just sides always with experience. It only does so when it thinks on balance that this gives an answer truer to the questioner’s intention. If specifically instructed to ignore the real world, and go with the logic, the right hemisphere is actually *better* able to do so than the left hemisphere.

Remember that, in the experiment of Deglin & Kinsbourne which I referred to, the question was not whether the syllogism was structurally correct – but whether the conclusion was *true*. And there the right hemisphere protested that the conclusion was not true, while the left hemisphere blithely accepted it as correct. However, in another kind of experiment, where the question is the very different one: ‘is this syllogism structurally correct?’, it is the right hemisphere which gets the answer correct, even when the conclusion flies in the face of one’s experience. The left hemisphere is distracted by the familiarity of what it already thinks it knows, and gets the answer wrong.²⁶³ According to Vinod Goel, one of the architects of that experiment, and one of the leading researchers in this area, ‘this conflict detection role of right lateral/dorsal prefrontal cortex is a generalized phenomenon that has been documented in a wide range of paradigms in the cognitive neuroscience literature’.²⁶⁴

To put it crudely, the right hemisphere is our bullshit detector. It is better at avoiding nonsense when asked to believe it, but it is also better at avoiding falling prey to local prejudice and just dismissing rational argument because the argument does not happen to agree with that prejudice.²⁶⁵

And the left hemisphere? ‘The left hemisphere’, according to Ramachandran, ‘is a conformist, largely indifferent to discrepancies,

whereas the right hemisphere is the opposite: highly sensitive to perturbation.’²⁶⁶ Elsewhere he says: ‘the left hemisphere’s job is to create a model and *maintain it at all costs*’.²⁶⁷ Older subjects, as it turns out – sad news for those of us who have opted to grow older – exhibit a greater belief bias than younger subjects, and rely less on the right lateral prefrontal cortex.²⁶⁸

According to Ramachandran, the left hemisphere adopts a theory, and then actually denies what doesn’t fit the theory.²⁶⁹ The evidence that this is the case is so extraordinary and compelling that we would not believe it if we had not already seen it. It will swear black is white. It’s not just intellectual matters over which the left hemisphere is in denial: ‘left-hemisphere denial may also involve the disappearance of much simpler visual percepts.’²⁷⁰ A nice optical illusion demonstrates this, according to Agnes Funk and Jack Pettigrew who have extensively researched motion-induced blindness. Though in itself trivial, it is at least memorably vivid. It can be found on the Wikipedia page for ‘motion-induced blindness’.²⁷¹ Three yellow dots are arranged against a rotating grid which *at no point* obscures them; yet, with fixation of gaze at the centre of the image, the dots continually disappear and reappear. The point made by the researchers, who studied the phenomenon, is that it is the product of interhemispheric rivalry: ‘the right hemisphere seems to adopt a veridical [true to reality] representation with appropriate weight given to all physical stimuli present’; whereas ‘the left hemisphere is likely to adopt an interpretation or hypothesis that is internally consistent, and then to deny discrepancies that do not fit with that interpretation.’ Hence the alternation: now you see it, now you don’t. The left hemisphere says ‘you shouldn’t be able to see that’ – and, as a result, you actually can’t: the right hemisphere says, ‘but it’s there’ – and so you can. The point is that, despite your being perfectly well able to see something, you can’t see it because of a theory that the left hemisphere has about it. ‘The left hemisphere seems to suppress sensory information that conflicts with its idea of what the world should be like’, writes John Whitfield: ‘the right sees the world how it really is.’²⁷²

The left hemisphere’s approach is theoretical, whereas ‘the right hemisphere plays a prominent role in detecting inconsistencies between hypotheses and reality.’²⁷³ Regions in the right hemisphere are active when subjects discover evidence indicating that their hypothesis may not be

correct,²⁷⁴ and it is the right hemisphere that updates the hypothesis according to the new, discrepant, information.²⁷⁵

To the extent that what I have had to say relies on imaging data, let me reassure the reader that the imaging results regarding right frontal activation for conflict detection are also strongly supported by lesion data,²⁷⁶ as is the role of right frontal activation in dealing with indeterminate information.²⁷⁷

Left hemisphere-damaged patients (whose right hemispheres were intact) were more inclined to modify the hypothesis they were working with when faced with new, conflicting evidence. In contrast, the right hemisphere-damaged patients (whose left hemispheres were intact) tended to maintain a hypothesis even in the face of negative feedback:²⁷⁸

When the right hemisphere is damaged, patients' hypotheses become rigid and impermeable to conflicting evidence ... These findings suggest that a functioning right hemisphere is necessary to detect inconsistencies and update flawed hypotheses accordingly.²⁷⁹

This touches on another familiar hemisphere difference – rigidity and flexibility. When problem-solving, it is the right hemisphere that is capable of set-shifting, rather than just, as the left hemisphere is inclined to do, opting for 'a more detailed version of the same state'.²⁸⁰ (On which hemisphere is better at generating new hypotheses the jury is still out.)²⁸¹

So both hemispheres contribute to both kinds of logic. That is intuitively understandable. While inductive logic is drawn from experience, not theory – a good start, involving both hemispheres – the left hemisphere's efficient use of what it considers facts can cause it to harden up its inferences into automatic, 'ready-to-go' responses, and thus the left hemisphere fails to detect situations where induction, importantly, breaks down: black swans. Problems calling for a search for counter-examples to conclusions recruit the right frontal pole.²⁸² It is the devil's advocate.

There are also situations where the premisses do not justify the conclusion that is drawn – not experientially, as in the case of Deglin & Kinsbourne's experiment, but logically – such as:

1. Either he is a college student or he is registered to vote (or both);
2. It is not true that he is both a college student and a regular golfer;

3. He is registered to vote.

In such cases, again, it is the right hemisphere that is the more important in deciding correctly the validity of whatever conclusion is drawn. Goel tested patients with unilateral frontal lobe lesions on their performance of a deductive task, while varying the completeness of information required to reach a valid conclusion. He found that patients with left prefrontal cortex lesions were selectively impaired in trials with complete information, whereas patients with right prefrontal cortex lesions were selectively impaired in trials with incomplete information. ²⁸³ Similar findings were made by two other studies of deduction, in which subjects were scanned while judging the correctness or otherwise of complex syllogisms that involved detecting incomplete or invalid arguments: in both it was the right posterior and frontal brain areas that appear to have been primarily engaged, rather than the usual left or bilateral prefrontal cortex activation. ²⁸⁴

As Goel and colleagues put it, the right prefrontal cortex has ‘a critical role’ to play in reasoning about incompletely specified situations, probably because it can maintain ‘ambiguous mental representations that temper premature over-interpretation by the left hemisphere.’ ²⁸⁵ In real life, few situations are completely specified, familiar or predictable – a problem that hangs over the research, because the difficulties in simulating the extent and importance of uncertainty encountered in real life within an artificial lab situation (pressing buttons in a scanner) are considerable. But, unlike the left hemisphere, the right hemisphere can operate with several types of uncertainties: inexactness, incompleteness, probabilities, fuzziness, observer error, and so on. ²⁸⁶

The prevalence of uncertain, incompletely specified, unfamiliar and unpredictable situations in real life lends strong support to Goel’s comment:

While the left prefrontal cortex is critical to reasoning processes, our data suggest that this is only half of the story. The right hemisphere, more particularly the right ventrolateral prefrontal cortex has critical roles to play in reasoning processes that go beyond ‘the perception of visual information’. One of these roles is to actively maintain indeterminate/incomplete patterns and prevent the left prefrontal

cortex from premature completion, until they can be fully evaluated
...

‘Premature over-interpretation’, ‘premature completion’: precise (from Latin *præ-cisus*) means ‘cut off before its time’? What this boils down to is that the left hemisphere specialises in jumping to conclusions. As a result, Goel emphasises that the misconception that the left hemisphere is dominant for reasoning and cognition in general must give way to ‘the importance of thinking in terms of hemispheric specialization’.²⁸⁷ When we come in Chapter 7 to look at cognitive intelligence, this will be amply confirmed.

What else discriminates the particular strengths of the two hemispheres? Bear in mind that the area is complex, the science young, and that conclusions must be tentative.

The psychologist and philosopher of cognition Philip Johnson-Laird foresaw right hemisphere participation in logical thinking before we had any scanning data to demonstrate it. This is because, he reasoned, the mind naturally solves problems *not* by working through rules in the abstract, but by imagining – sometimes a *visual* image, sometimes not. We construct a whole context, whether a scene or story, and see what it implies, whether it coheres in real-world terms, and seek alternatives if it doesn’t. ²⁸⁸ Several studies have shown that damage to the right hemisphere impairs not only patients’ ability to make logical inferences, as one might expect from the major role in interpreting human situations played by the right hemisphere, but to understand propositions involving *logical connectives*. For example, people without a properly functioning right hemisphere can still solve problems such as:

John is taller than Bill. Who is taller?

Arthur is taller than Bill. Bill is taller than Charles. Who is tallest?

But not:

John is taller than Bill. Who is shorter?

Arthur is taller than Bill. Bill is taller than Charles. Who is shortest? ²⁸⁹

In formal terminology, they have problems in deducing the ‘converse of relations’. In other words reversing relationships. It is tempting to think that this is largely because the problem is visualised – three men in a row – traditionally considered a strength of the right hemisphere; and there are indeed the expected reports of impaired reasoning on spatial relational problems by patients with right hemisphere damage.²⁹⁰ But right hemisphere reasoning can also be based on a scenario where the crucial piece of evidence is not only not visual, but has no perceptible correlate. For example, patients with right hemisphere damage find it hard to understand the following situation, and to make logical inferences about it:

1. Sally approached the movie star with pen and paper in hand.
2. She was writing an article about famous people's views about nuclear power.

Normal individuals are likely to infer that Sally wanted to ask the star about nuclear power; but patients with damage to the right hemisphere infer that Sally wanted the movie star's autograph.²⁹¹ They seize on the first sentence, make a quick and dirty inference, and then can't let go. Similarly, when shown moral choice scenarios,

split-brain patients' left hemispheres formed quick-and-dirty inferences when presented with initial evidence about the scenario (the potential danger of the situation), and these inferences were resistant to revision when additional evidence about the characters' intentions was provided.²⁹²

It is the left hemisphere that is adept at ‘prematurely locking onto precise concrete patterns, and quickly drawing conclusions, albeit substandard ones’.²⁹³

In fact deductive logic is significantly associated with an area best known for its role in emotion and feeling, the right ventromedial prefrontal

cortex.²⁹⁴ People with damage to this area can't see what other people intend, or what purposes they have. And seeing what follows from a social, emotional understanding of the situation in which one finds oneself in the real world is at least as important as seeing what follows from an abstract proposition. Indeed understandably enough, if a task involves arbitrary material, most people's performance is relatively poor. We are intentional beings with purposes. Our thoughts and actions have contexts and ends. So it is not surprising to learn that the presence of meaningful content dramatically improves that performance.²⁹⁵ This is well illustrated by the so-called Wason tests (discussed in Chapter 18).

For what it's worth, deductive reasoning can be broken down into at least three categories which, it has been suggested, may have differing brain correlates. Relational arguments (A is to the left of B; B is to the left of C; therefore A is to the left of C) require right hemisphere involvement. Categorical arguments (all As are Bs; all Bs are Cs; therefore all As are Cs) require left hemisphere involvement, as do propositional arguments (if there is an A, then there is a B; there is an A, therefore there is a B). All this is exactly what we would expect given the relational mode of the right hemisphere, and the categorising and linear, propositional mode of the left hemisphere. However this needs to be heavily qualified, in ways that make sense in the light of what we know of the overall approaches of the two hemispheres.²⁹⁶

For example, a hemisphere difference with which we are already familiar also plays a part: the left hemisphere's limited capacity to deal with what is not explicit. More explicit reasoning is underwritten by the left hemisphere, less explicit reasoning (such as is often involved in problem-solving, including scientific and mathematical problem-solving) by the right hemisphere. This is an important part of what we call 'insight', the ability to see suddenly to the core of a problem, when it is not obvious, and resolve it, a process often accompanied by an 'aha' moment. Such moments of insight are robustly associated with activity in the right amygdala, an ancient, deep-lying structure involved in emotional reactions, and the right anterior superior temporal gyrus.²⁹⁷ This kind of problem-solving may be impaired by too much consciousness of the process: rendering one's thought processes explicit, or analysing a judgment, encourages the left hemisphere's focus on the explicit, superficial structure of the problem, at the expense of its depth.²⁹⁸

Everyday problem-solving requires both hemispheres. A good example is deduction: some steps need to be followed (LH), but the solution may still come as a revelation (RH). A comparison of deduction with probabilistic reasoning found that 70% of the subjects noted sudden insight, an ‘aha’ moment, during deduction, while, by contrast, 80% described ‘probabilistic reasoning’, effectively induction, as involving ‘the gradual stabilisation of judgment’. Simultaneous brain scans revealed activation of the right amygdala (but not the left) in the deduction task, which relied predominantly on right hemisphere structures in this study, but no amygdala activation (either left or right) during the probability task.²⁹⁹

The extent to which the reasoning problem relies on interpreting syntax governs the degree to which the left hemisphere is involved – one problem with all the findings in this area is knowing how much of what seems to be a left hemisphere predominance is due to the often semantic-syntactic elements of the exercise that is being assessed.³⁰⁰ But, contrary to received opinion, much reasoning takes place outside language.³⁰¹ Thus, according to Ribeiro and colleagues, the right hemisphere is ‘the *main* region responsible’ for making logical or pragmatic inferences, particularly where the stimuli are visual rather than lexical.³⁰² There is a right hemisphere superiority for the detection and application of an underlying principle or pattern in the absence of verbal awareness (a common component of intelligence tests, and of the GCHQ aptitude tests). Thus, for example, where the colour of a number flashed on a screen predicts something about the number that follows, it is the right hemisphere that is better able to detect the rule. Indeed before we are aware of there being a rule or principle at all, the right hemisphere has clocked it.³⁰³

This is pattern recognition, at which the right hemisphere excels. It is also the basis of all scientific thought.³⁰⁴ And, outside of the world of puzzle books and psychological experiments, right frontal and temporal cortex play a critical role in understanding and inferring the true meaning in *context*, even where there is a key role for language.³⁰⁵

The left hemisphere language regions (including Broca’s and Wernicke’s areas) and parts of the prefrontal cortex have been repeatedly implicated in studies of inferencing.³⁰⁶ An unbridled tendency to draw inferences is one reason that the left hemisphere is far more open to delusion than the right, by a factor of about 3:1 (and that is, in all

probability, an understatement of the case). As Claude Braun and Sabrina Suffren have shown, it is not so much that there are perceptual or cognitive deficits after right hemisphere damage, though indeed there are, as that the unbridled cognitive propensities of the left hemisphere, specifically jumping to conclusions and excessive reference to the self, lead to delusional thinking.³⁰⁷

Reasoning and calculation are not the same thing. Regions in the *right* prefrontal cortex and inferior parietal lobe are more active for reasoning than for calculation, but regions in the *left* prefrontal cortex and superior parietal lobe are more active for calculation than for reasoning.³⁰⁸ This is partly because of the left hemisphere's being superior at multiplication, since it has ready access to the 'times tables', which are verbal recitations used in such calculations.

But there is a broader, and highly significant, underlying principle here. The left hemisphere is very good at carrying out procedures (calculation), less good at understanding the real-world meaning of the procedure. The right hemisphere not only encodes verbal stimuli more veridically than the left hemisphere:³⁰⁹ despite the clear general advantage for the left hemisphere in processing verbal material, the right hemisphere has the advantage in language *comprehension*. That might surprise you, until you realise that understanding requires retention and integration of different types of verbal information over long time spans, and the ability to revise as new words are encountered and integrated with the prior context. For lengthy sentences or paragraphs and longer discourses, this task becomes more difficult, as the amount of information that is extracted grows and as earlier material must be remembered, and perhaps reassessed over longer time intervals.³¹⁰ For a range of reasons, including having a longer working memory,³¹¹ more sustained attention, a better grasp of the whole, greater sensitivity to context, a greater capacity to understand implicit meaning, a greater degree of flexibility and willingness to revise assumptions, the right hemisphere has the advantage.³¹² The right ventrolateral prefrontal cortex is also important for monitoring whether an action is appropriate in context, and preventing it happen when it isn't.³¹³

Thus, to sum up, one can say the following with some degree of conviction. The left hemisphere has difficulty recasting the information given, or coping with incomplete or contradictory information. It jumps to

conclusions, fails to get the point of a story, fails to understand what is going on in someone else's mind, is unable 'to make implicit inferences establishing coherence, to grasp the force of indirect illocutions such as requests',³¹⁴ and thus to make logical inferences from what it is told. Where the circumstances are familiar, the problem is determinate and explicit, the situation is congruent with one's belief bias, and the presentation is lexical, there is a clear left hemisphere advantage in reasoning. But where the circumstances are unfamiliar, indeterminate or implicit, challenge one's bias, or are not expressed in primarily lexical terms – or require interpretation in the light of context – there will be a critical role for the right hemisphere.³¹⁵

Since the whole point of my exploration of reason is to see the extent to which it can be relied on for truth, let me finish with some further considerations on the topic.

According to Michael Gazzaniga, the left hemisphere 'is constantly looking for order and reason, even when there is none – which leads it continually to make mistakes. It tends to over-generalize, frequently constructing a potential past as opposed to a true one.'³¹⁶ My model, says the left hemisphere, is better than your reality: in the canonical, theoretical world of general abstractions, things should work out according to my plan. But then reality, with all its messy complexities and differences, gets in the way and spoils the story.

The left hemisphere is more likely to act on its theory as though it represented reality. A very important aspect of the real world is that in it nothing happens in isolation. Everything exists only in relation to an indescribably rich and complex nexus of other things, some of which modify whatever happens to be the 'target' of our attention by their very presence. Equally they will be changed by our intervention and, in turn, will change the nature and direction of the intervention itself. In other words there is never a truth without a context with which it interacts: there is a context for everything in the real world. In the theory that gets left out.

Part of the problem is the left hemisphere's reluctance to confess when it is nonplussed. Its self-belief is a problem: it believes its own propaganda. It often does the 'smart' thing – which is, in actuality, not as smart as it looks. As we know it hates uncertainty; and according to Gazzaniga's research team, 'the left hemisphere tends to create inferences and explanations to resolve uncertainty'. Meanwhile, as they put it, 'unlike the

left hemisphere, the right hemisphere, in our view, places a premium on the truth.’³¹⁷

For example, in a simple task requiring the participant to predict which of two stimuli will appear on a given trial, say a green light or a red light, the isolated left hemisphere of split-brain patients attempted to distribute its responses in a way that matched the probability with which each stimulus appeared. So if it seemed that red came up two-thirds of the time, it would randomly predict red on two-thirds of occasions and green on the other third. That may sound smart, but it’s illogical. You don’t know ahead of time which individual stimulus will be which, and you end up scoring at chance level. The correct solution is to choose red every time, since it is always more likely. And this is exactly what the right hemisphere does, thus maximising the number of correct responses.³¹⁸ This, interestingly, relates to the difference between a generalisation, something that is predictable (red 66%, green 33%), with which the left hemisphere deals; and a unique instance, which is therefore unpredictable (and is always either red or green, not 66% red and/or 33% green), with which the right hemisphere deals.

In another study, when the experimenters rigged things, so that, after a while, whatever guess the left hemisphere made it received the encouraging response that it had chosen correctly, it confidently asserted that that was because it had at long last cracked the formula.³¹⁹ Er – bullshit.

SUMMARY

Virtually all delusional syndromes are more commonly the result of right hemisphere than left hemisphere dysfunction; the degree to which this is the case is broadly proportional to the bizarre nature of the delusion involved; and no delusional syndrome is commoner in left than right hemisphere dysfunction. Insight into delusional thinking is dependent on the right hemisphere. In general, right hemisphere memory is more veridical than left hemisphere memory. Both hemispheres play a part in reasoning, and when the situation is relatively simple, completely specified and the outcome in accord with expectation, the left hemisphere plays the key role; when any of these conditions does not apply, the right hemisphere is more reliable and veridical.

Overall, in general it is the judgments on reality made by the right hemisphere that are more reliable.

APPREHENSION

Rushing into action, you fail. Trying to grasp things, you lose them.

—Lao Tzu ¹

WE'VE HEARD A LOT ABOUT WHAT HAPPENS AFTER RIGHT HEMISPHERE damage. But what happens after damage to the left hemisphere?

The twentieth-century psychiatrist Friedrich Rothschild wrote perceptively that the human body manifested

a difference, which constitutes an expression of the ultimate primordial fact of life, the opposition, the duality, or better the polarity, of the individual and the world. *The left side of the body serves more as the place of receptivity and action for whatever is other than ourselves, the right side serves more those active life expressions that emerge from one's individual self.* The polarity of individual and cosmos has its counterpart in the polarity of right and left; that is the meaning we believe we can see in the structure of the body.²

Thus, he thought, while the right hemisphere responds to the realm of the world beyond the self, the left hemisphere expresses the will of the ego acting on the world. And since, as we have seen, the key advance of the left hemisphere in humans was to enable us to manipulate the world vastly more effectively than other animals, the consequences of damage should

largely have to do with our capacity for *utilisation*. In the left hemisphere this could be said to be *ap-prehending* (from Latin *ad* + *prehendere*, to hold *onto*) the world, and in the right *com-prehending* (from *cum* + *prehendere*, to hold *together*) the world.

Speech arose in humans in an area of the left frontal cortex, called Broca's area, which lies just next to the area that controls movement of the right hand. Indeed it is widely thought that language developed, in part, from gesture. This speech area has been found to be activated even by grasp and manipulation, and is constantly involved in the production of meaningful gestures.³ Equally, restricting hand movements impairs verbal fluency.⁴ Speech and pointing develop together in infants: the child 'always points while naming and does not name without pointing – stretching out the right hand', according to Marcel Kinsbourne.⁵ Most remarkable of all, as mentioned, patients born without arms can nonetheless experience phantom upper limbs; VS Ramachandran describes the case of just such a woman who experienced uncontrollable gesticulation by her phantom limbs.⁶ Once again, it looks as if there must be some morphogenetic schema that is innate. Detailed phantom limbs are not infrequently reported by people born without limbs.

In most languages, the words we use to describe language processes derive from the right hand: we say we 'grasp' the meaning, and so on.⁷ The connexion lies deep in our minds and in our brains. What would be the likely consequences of a left hemisphere stroke or other insult? In the first instance, this would be an impairment of utilisation, by means of the right hand; and in the second, of utilisation through language, which yields a virtual, easily manipulated, version of the world in which we can test out possible strategies and issue instructions. Language and the hand turn out to have a lot more in common than just being next-door neighbours in the brain. In left hemisphere damage, the two most serious consequences are motor impairments, particularly of the right arm and hand; and language impairments.

Let's begin with the right hand. Problems with the hand are not just those of damage to the left primary motor cortex itself causing difficulty moving the right hand and arm, in exactly the same way that damage to the right motor cortex causes difficulty moving the left hand and arm. I am referring to something *cognitive*, over and above the motor level, to do with readily usable daily objects, such as tools.

One of the first detailed descriptions is by the great Czech neurologist, Arnold Pick, over a hundred years ago. His patient Salamoun, who had suffered a left hemisphere stroke, had problems using simple everyday objects such as matches, keys, a hammer, or a razor. Here he is, trying to light a pipe:

The patient is given a pipe and brings it correctly to his mouth, then expertly reaches for the tobacco pouch and takes a match from the box but when asked to light it, sticks the head of the match into the mouth piece and puts the other end in his mouth as if to smoke it. Then he takes it out of his mouth, draws it out of the mouth piece and sticks the *other* end of the match in the mouth piece of the pipe, pulls it out again, holds it for a while in his hand apparently thinking, and then puts it away.⁸

Intriguing. Notice that Salamoun is not generally cack-handed: he goes through a sequence of actions fluently, even ‘expertly’, up to a certain point. He understands what he needs and wants to do, and he gets as far as actually taking the match in his hand – then is suddenly lost. But it is not that the sequence that leads up to it is more practised than the striking of the match itself: in fact the striking of the match is probably the most practised and automatic action of all. Yet it is the *use* of the match that stumps him.

Another patient, described by the French physician Joseph Morlaas, showed related problems:

For example, we give the patient a pair of scissors; she says ‘scissors’ correctly [ie she recognises the object, knows, in the normal sense, what it is]. We ask her to write, and she uses the scissors as a pen and is amazed that no letter can be seen.

Morlaas called it *l’agnosie d’utilisation*, a not knowing how to *use* objects.⁹ Nowadays this is usually called ‘ideomotor apraxia’, and it is a frequent consequence of damage to the left parietal or premotor areas. It is characterised by an inability, on command, to carry out a simple action in relation to an object of use – a comb, a toothbrush or a hammer, for example – or to imitate its use, though the action can usually be carried out

spontaneously (ie, when conscious will is less involved). Such damage renders the sufferer incapable of using a hammer and nail, or a key and a padlock, a match or a pair of scissors, at least when consciously obliged to do so, whereas right hemisphere damage leaves the ability to use simple tools unaltered.

By contrast, difficulty in conceiving a task as a whole, usually involving a succession of processes, is called 'ideational apraxia', and it can occur after left, right or bilateral lesions.¹⁰ Right hemisphere damage only rarely impairs tool use, but is often involved where there is difficulty with a naturalistic action involving a sequence of steps – for example, making a cup of coffee, or wrapping a present, which are not so much about how to use an object as how to achieve an end.¹¹ Other apraxias, such as involve getting dressed ('dressing apraxia', a three-dimensional spatial task relating to the body) or construction ('constructional apraxia', putting together the parts of an object to build a whole, or drawing an object in space), are usually associated, as one might expect, with lesions in the right hemisphere, not the left.

I have suggested that the division of the brain arises from the need to attend in two radically distinct ways to the world at once. This can be seen, once again, in the human hand.

When the movements of the right hand are no longer inhibited by the left frontal cortex, it can't be prevented from making random grasping actions. Following loss of inhibitory control through stroke – what is known as a 'release' phenomenon – one woman found that her right hand would tend spontaneously to reach out and grasp objects (eg, door knobs) that she passed; in another case the hand would randomly pick up a pencil and start writing.¹² A right-handed patient who had suffered infarction of the left medial frontal cortex had troublesome spontaneous grasping which he could no longer inhibit.¹³ Another, again after a left frontal stroke, found her right hand

showed an uncontrollable tendency to reach out and take hold of objects and then be unable to release them. The patient would repeatedly express astonishment at these actions. At times the right hand interfered with tasks being performed by the left hand, and she

attempted to restrain it by wedging it between her legs or by holding or slapping it with the left hand. ¹⁴

It is the left hemisphere that controls the right hand, which, for most of us, is the one that grasps things, and when frontal control is lost, the right hand grasps automatically and at random. This is true in left-handers, too – the concept of grasping is separate, therefore, from control of the hand as such. ¹⁵

By contrast, the concern of the right hemisphere is exploration, not grasp. In a mirror image of the finding just referred to, exploration of space, even with the right hand in a right-hander, extraordinarily enough specifically elicits activity in the *right* hemisphere. That it is the *exploratory nature of the action* which matters is made clear by contrasting grasp and exploration. During grasp, activations occur as expected, in the left hemisphere. Strikingly, however, ‘during exploratory movements [still of the right hand]... all areas of activation were in the *right* hemisphere’, despite this being on the same side as the hand being used and the area of space being explored. ¹⁶ And this finding is not confined to humans: when great apes, and monkeys, want to utilise inanimate objects, they reach out with the right hand (left hemisphere). Yet they reach out the left hand (right hemisphere) towards living things. ¹⁷

Here we see a radical distinction between the hemispheres: in the right hemisphere, exploring the world, on a level with it; versus seizing hold, and taking control, of the world, in the left. The right prefrontal cortex is in fact essential to meaningful exploration. ¹⁸

So much for the hand. But what about language, that huge, and hugely important, area in which left hemisphere damage is principally manifested, whether in its reception or expression, oral or written? What is language, after all?

The nature and purpose of language is a large topic, and my thoughts on the subject have been elaborated elsewhere. ¹⁹ In *The Master and his Emissary* I argued that language is neither necessary for communication – not even for some highly sophisticated kinds of communication; nor for thinking – not even for some highly sophisticated kinds of thinking; although, since we have it, it is clearly involved in some aspects of both.

I also discussed the position held by many prominent anthropologists, going back to Herder and Rousseau in the eighteenth century, and echoed by von Humboldt and Jespersen, in the nineteenth and twentieth, that to the extent that language is used for communication it probably began as a form of music, deeply rooted in emotion and the body – the most expressive aspects of language still are its ‘musical’ qualities, pitch variations, intonation, rhythm, speed, volume and flow; and that it approximated the rather more abstract and symbolic nature of language as we now know it by degrees, beginning in the right hemisphere, as language still does in children, and gradually crossing to the left hemisphere, leaving music behind in the regions of the right hemisphere that are homologous to the ‘language areas’ of the left. My own view is that formal language was required, possibly as an effect of the increasing size of social groups, only when I–Thou relationships ceded gradually to I–It relationships. It enabled ‘me’ to communicate with ‘you’ not just about ‘us’, but about an object or third party, ‘over there’ or currently not present, on which, or on whom, we might have designs.

But another way of thinking suggests that language may not be about communication, primarily, at all. It may instead be a way of mapping the world – a system of symbols that reflects the world. Words, according to this view, are tokens for things, and grammar a schema of how they relate, enabling us to plan a strategy and manipulate more effectively. As a map enables us to see things that just living headlong ‘at ground level’ would never allow us to see, so language, the manipulation of those symbols, enables us to see, as if ‘from above’, what the overwhelming impact of immediate experience hides from us. It enables alternative hypotheses to be compared and examined for their projected consequences. We can, for the first time, go ‘offline’ and play with the shapes. I have compared the left hemisphere’s use of language to a general’s strategic campaign map of the *territory*, which has the important facts for the purpose clearly flagged, but leaves out almost everything of the reality in the *terrain* it maps. In a map, that is not a weakness, but precisely the source of its strength and usefulness.

Of course, the analogy of language with a map goes only so far. Language is a highly complex system, a constantly emerging, and evolving, organism, an embodied aspect of experience, caught up in the fluidity of the reality it reflects. And from the commerce between symbols and what they

symbolise two things inevitably follow. In the left hemisphere's world words are seen as arbitrary signs: in the right hemisphere's world they are seen as to some extent fused with the aspect of reality they represent.

In other words, tokens or symbols cannot escape being part of the real world in the right hemisphere, and the real world cannot escape becoming tokens or symbols in the left hemisphere. Thus subjects with their left hemisphere experimentally suppressed reported that the sun was so named 'because it shines', bread because it is 'so tasty and fresh', spaghetti because it's 'what you eat with cheese'. They couldn't accept that objects might be renamed; the name was part of what they *were*. By contrast, with the right hemisphere suppressed, subjects took the view that names are entirely arbitrary.²⁰ (Although de Saussure taught that the sign is arbitrary, it is not.)²¹

Incidentally, there is a fascinating passage in Hugo Karl Liepmann's account of his patient T, a 48 year-old government official who suffered a stroke, resulting in damage to higher cognitive centres in the left hemisphere, and a release phenomenon in the right hand. Liepmann records this 'remarkable fact':

When required to indicate objects in a picture, he points correctly with the left hand but frequently moves the right hand as if he wanted to grasp the pictured object. He attempts in a way to take it from the sheet. His behaviour is as if he had the illusion that the pictured object was physically real.²²

This patient simultaneously exhibits an *increase in the sense of reality* of what is merely a representation, due to left hemisphere damage, and the grasp reflex of the right hand.

According to a view which has been much promulgated in recent years, language is just a system of signs, in which words refer endlessly to one another (a typical left hemisphere view). However language is ultimately like another token system, money. Its value cannot lie purely in referring to itself. Money means something only in terms of an underlying reality: it begins with real-world items – someone's cows, hens or corn somewhere – and eventually it is returned to real-world items – groceries, car repairs or cinema tickets – somewhere else, however many 'virtual' transactions it

may become involved in along the way. According to the narrow view and the short-term view that characterises the approach of the left hemisphere, money appears to have value in itself, to be an end in itself. But from the broader, long-term view that characterises the approach of the right hemisphere, this is clearly a mistake.

So it is with language. All language is metaphoric in nature. All meaning eventually arises from personal experience in the body; and language – including, and especially clearly, philosophical and scientific language – metaphorises bodily experience, however *abstract* (literally ‘dragged away’) its *discourse* (literally ‘running to and fro’) may appear. It is metaphor alone (the word itself is a metaphor: it means one that ‘carries across’) that can carry us across the apparent gap between language and the real lived world. The meaning of language begins and ends in the body – where it ‘cashes out’ in experience.

As I have suggested language, like everything else, has its left hemisphere aspects and its right hemisphere aspects. It is to be expected that these will reflect the nature of the two hemispheres’ worlds – and they do. There are three aspects of language that especially tether language to the lived world and to the body: metaphor, ‘prosody’ (the music of the voice, its inflection and intonation) and ‘pragmatics’ (the understanding of an utterance as a whole in its real-world context). All three are primarily right hemisphere-dependent. Perceptual links between words – another ‘real-world’ element – are also made primarily by the right hemisphere.²³ By contrast semantics and syntax – the tokens as such and the internally validating rules whereby they relate, within the system – are primarily (though not exclusively) left hemisphere-dependent.

The left hemisphere has a much more extensive vocabulary than the right, and more subtle and complex syntax. It extends vastly our power to map the world and to explore the complexities of the causal relationships between things. This is surely its *raison d’être*, and it is valuable to a predator, at least in simple circumstances, where there are not many factors, as there almost always are once one starts taking the broader view.

But this superiority has nothing to do with a greater affinity in the left hemisphere for language *per se* – with words or auditory material. Rather the left hemisphere’s superiority for language stems from its being the hemisphere of *representation*, in which *signs are substituted for experience*.

You might imagine that the usual right hemisphere predominance for recognition of facial expressions should also apply to lip-reading. But not at all.²⁴ Equally you could be forgiven for thinking that sign language, which is visuo-spatial rather than verbal in nature, had an affinity with the right hemisphere, rather than the left. But sign language, just like verbal language, is left hemisphere mediated;²⁵ and left hemisphere damage in just the areas that cause problems for hearing subjects causes disruption in sign language for deaf subjects.²⁶ This proves that the specialisation of what is called the ‘auditory cortex’ of the left hemisphere is not to do primarily with the processing of auditory material, or even of words as such. It is to do with the processing of signs, tokens, *representations* of things, whether these be verbal or visuo-spatial. This also, by the way, explains the otherwise baffling expansion of the so-called ‘language’ areas in the brains of primates, who nonetheless cannot be taught language: they begin the process of mapping the world in signs or symbols.

Equally, I believe, the visuo-spatial superiority of the right hemisphere is probably not about visuo-spatial qualities in themselves, but simply that vision has become the most important of the human senses, and is by now for most of us the main means of perception of the actual, of things *present in and of themselves* (in as much as such a thing is still possible) as opposed to their signs.

Apart from a range of problems purely to do with language and with the right hand, there are two syndromes that occur typically after left, rather than right, hemisphere damage.

One is called Gerstmann’s syndrome. Its very existence is controversial and it was famously described by AL Benton as ‘an artefact of defective and biased observation having little support for its alleged focal diagnostic significance’, before being trenchantly critiqued by the formidable Macdonald Critchley a few years later.²⁷ However, what concerns us is not whether it constitutes a syndrome (it may or may not), but whether its posited constituent parts are common consequences of left, rather than right, hemisphere damage – which they indisputably are.

What are they? There are four elements: difficulties with writing (dysgraphia), with calculating (dyscalculia), and with right–left orientation, together with difficulty identifying one’s fingers by name (finger agnosia). Let’s look at them in turn.

Difficulty writing, given the manifest problems in left hemisphere stroke of language and using the right hand, can hardly count as a surprise; nor can difficulty calculating, since we have established that certain types of calculation, or symbol manipulation, are the sort of thing we expect the left hemisphere to provide under normal circumstances – particularly multiplication, which relies on implicit recitation of the ‘times tables’. As for right–left disorientation, when formally tested under optimal conditions, a random sample of medical students were right–left disorientated 23% of the time, which accords with other figures suggesting that about 20–25% of the general population is right–left disorientated much of the time.²⁸ No other part of a neurological syndrome has such a high hit-rate among the normal population, and it can be reasonably doubted whether it could act as a diagnostic criterion for anything. In any case, this is almost certainly a problem in labelling, or naming – in other words, a linguistic, or at the very least a symbolic, problem.²⁹

Which leaves the question of difficulty naming one’s fingers, or recognising and responding to them by name – so-called finger agnosia. And that, in turn, leads neatly into the second syndrome (other than Gerstmann’s syndrome, if it exists) which is almost always identified with left hemisphere damage.³⁰ It will be remembered that, though the left hemisphere does not have a good sense of the body as an integrated entity, it does have dominion over the body as an assemblage of parts. This explains a condition called autotopagnosia (from Greek, *auto-*, self, + *topos*, place, + *gnosis*, knowledge) sometimes also called, especially in the Spanish literature, ‘autotopoagnosia’. The term refers to an inability to locate, on demand, body parts either on one’s own body, or on another body, or in a picture, when they are named by an examiner. It seems to follow damage to the left posterior parietal cortex, or underlying subcortical regions.³¹

The condition manifests itself not spontaneously but in response to questioning. In ordinary conversation, subjects use the names of body parts appropriately. For example, a man who could not point to his ankle on demand, later remarked spontaneously, ‘I always told my sons not to play football, since sooner or later they would break their ankles’.³² It is when asked to name or to point to a body part in response to its name that the condition becomes apparent. The most frequent errors are pointing to a body part next to the one intended, or to one semantically related to it. The

deficit is in naming and in describing the functions of body parts, or in determining their spatial relationships.³³ It has generally been attributed either to a linguistic impairment, or to the inability to analyse a whole into its parts, or both. Here is one of the most striking examples reported in the literature:

'Where is the mouth?' 'The mouth is in the upper half of the body; it is the seat of speech ...' *'Is it above or below the nose?'* 'Well ... it is difficult to say exactly ... this is the kind of thing that slips my memory.' *'Above or below?'* 'I would say above, but I am not sure.' ... The finding, however, that the patient failed not only in pointing to body parts, but also in pointing to parts of a bicycle, strongly argues against [the assumption that it concerns only the body] and indicates that the disorder extends well beyond the realm of awareness of the human body... The hypothesis is, therefore, advanced that the basic disturbance was the inability to analyse a whole into its parts... ³⁴

Nonetheless, two other cases suggest that the problem is commonly limited to body parts.³⁵ And, from a much earlier case, from Gottfried Engerth in the 1930s, one sees very clearly preserved overall form, coupled with impairment of parts:

Fig. 16. Drawings of (a) a person, a horse and (b) a hand, by a subject with autotopagnosia (from Engerth 1933)

As you can see (fig a), the subject is able to draw the idea of a horse and a person (though there is some element of right visual field hemineglect, interestingly enough, in both), especially when you consider that he is using his unaccustomed hand to draw. But his attempt to draw a hand is hopeless (fig b). Notice that it is the *hand* in particular – as one can also see from the fact that the person (fig a) has an arm that ends in something like a wheel, not a hand (and perhaps that the horse’s hind hoofs are neglected).³⁶

When the left hemisphere is damaged, the representational system of language may fail, with potentially devastating consequences for someone living in a culture where the word is all-important. But the things that are represented are still there, of course, and can often be summoned to the mind by the word: it is usually extracting the word from memory and uttering it that seems to present the problem. Joseph Lange describes a woman with alexia, inability to read, following a stroke: what is so arresting is that though the word is lost, the real-world referent shines through. The import of the word has been understood, though it itself can be recovered only with huge difficulty. Instead of reading ‘India’ she reads ‘elephant’;

instead of 'Reichstag' she reads 'Berlin' – and carries on to describe the scene at the Reichstag. In other words at the implicit level she has understood the significance of the word, but she can't read it. Similarly:

At first she cannot read the word Goethe but states, 'It is a man, a poet, I know but I can't name him. Uhland – no, not Uhland, he belongs in the Biedermeier period.' She then spells G, a, l, and then stops while spelling and calls out liberated, 'It is Goethe!' ³⁷

This is just more evidence that human hemisphere difference could be seen as that between the experienced world (right hemisphere) and the virtual world (left hemisphere). The left hemisphere's strength in humans, because of the development of the frontal lobes, has become this: given data, it can manipulate it in certain ways highly efficiently. But it isn't good, any longer, at understanding what the data mean in real-world terms, a fact demonstrated by its tenuous hold on reality when the right hemisphere is no longer fully functioning, as we have seen, and shall further see.

Just as it is the right hemisphere that understands the overall meaning of an utterance, taken as a whole, while the left hemisphere has a better grasp of the rule book of grammar, it is, perhaps surprisingly to some, the right hemisphere that has the better intuitive sense of numbers and their relative size.³⁸ However, the sense is approximate. By contrast, the left hemisphere has precision, but it lacks the same intuitive sense of what it is actually doing, other than following rules and manipulating symbols.³⁹

SUMMARY

Left hemisphere dysfunction does not change the world radically in the way that right hemisphere dysfunction does. Rather, it presents impediments to fluent utilisation of the world, either through the right hand or through language: the problem is not one of understanding (*comprehension*), but of manipulating (*apprehension*), the world. The fabric of reality typically goes for the most part unaltered when the left hemisphere is suppressed.

EMOTIONAL AND SOCIAL INTELLIGENCE

Anyone who wants to be all head is as much a monster as one who wants to be all heart.

—*Johann Gottfried Herder*¹

AS I WRITE, AN ‘IN DEPTH’ SURVEY OF RIGHT HEMISPHERE FUNCTIONS confirms, if confirmation were needed, the drift of the previous chapters: that the right hemisphere’s mode of attention, capacity for pragmatic understanding and communication, superior perceptual integration, and ability to shift belief appropriately in the light of new evidence, all make possible what the authors refer to as the ‘right hemisphere-dominated grip on reality’, a grip that ‘becomes increasingly tenuous the more impaired these functions become’.²

What we have not yet talked about, however, is the intuitive sense of reality itself, and the impact of emotional awareness on the capacity to understand what is happening in the world. If the left hemisphere, as we will see Jaak Panksepp suggests, tends to lie about emotional matters, it may be, as much as anything, because it simply does not understand what it is dealing with. But I don’t discount Panksepp’s hint that there may be more to it than that.

THE SENSE OF REALITY

It would be hardly surprising if abnormal activity or deficits, regardless of hemisphere, were to lead to changes in something so hard to pin down as the sense of reality itself. However, there are several indications that such phenomena are more common when there are abnormalities in the right hemisphere.

The first thing that springs to mind is that some patients who actually report a diminished 'sense of reality' have impairments of function predominantly in the right hemisphere,³ show cortical thinning in various regions in the right hemisphere,⁴ and exhibit grey matter volume reductions in the right hemisphere, together with volume increases mainly in the left hemisphere.⁵

A diminished sense of reality is a very common experience in schizophrenia, a syndrome that, as I have suggested, closely resembles aspects of a right hemisphere deficit syndrome. It can be so pervasive that patients believe that nothing is real, all is play-acting. In hospital, patients often believe that the doctors and nurses are actors, the ward is a stage set, everything a *representation* of reality, not reality itself. This has some elements in common with Capgras syndrome, in which familiar people have been replaced by impostors, a syndrome almost always involving dysfunction in the right temporoparietal region, as we have seen.

Additionally, borderline personality disorder, in which there is a grossly diminished sense of the self and of the reality of the external world, is related to reduced size of the right parietal lobe, and enlargement of the left hemisphere in the region of the postcentral gyrus.⁶ Elevated levels of perfusion in the left temporal lobe are found in the closely related, indeed overlapping, condition of dissociative identity disorder.⁷ A patient with borderline personality disorder marked by severe self-mutilation, sense of futility and tendency to manipulate others ceased to exhibit the symptoms after a left frontotemporal injury sustained in a suicide attempt.⁸ A study of a patient with the rare Kleine-Levin syndrome, in whom the primary disturbance was a pervasive sense of unreality, implicated deficits in the right hemisphere.⁹

Lesions that give rise to epileptic phenomena are a special case. This is because it is difficult to know if dysfunction of brain tissue leads to a diminution, or its excitability to an exaggeration, of the experience with which that cortical area is commonly associated: either can occur.¹⁰

Be that as it may, EEG measures and electrodermal response amplitudes and frequencies show greater activity in the left hemisphere in schizophrenia compared to normal subjects. (As expected, the reverse picture is found in depression, with greater activity in the right hemisphere and lower in the left hemisphere than in normal subjects.)¹¹ This is in keeping with the phenomenological picture in schizophrenia, which resembles one of abnormal and exaggerated left hemisphere function. Similarly, looking at it the other way round, left hemisphere epileptic discharges produce schizophrenic-like psychotic symptoms.¹² Here is evidence to suggest that abnormal electrical activity intensifies the experience associated with the cortex. But in other cases the spontaneous excitability of the cortex is itself a sign that the underlying cortex is damaged and incapable of functioning normally.

For this reason, intriguing as these particular cases are, it is often hard to know how to interpret them with any confidence, although other evidence can sometimes point to the more likely explanation in any one case. In the sequence of perioperative cases referred to earlier, Mullan & Penfield describe two people who experienced what the authors call 'illusions of greater awareness', or a heightened sense of reality. Both had right hemisphere lesions: in one case it appeared to involve paroxysmal excitation of the right hemisphere, and in fact it is recorded that artificial stimulation, at operation, of the affected area gave rise in the patient to the sense of intensified awareness, making the interpretation of this case more straightforward. By stimulating the right hemisphere, the patient had a heightened sense of 'smells, sounds, visible objects, and pressures'. He called it 'new awareness' of whatever he was experiencing, whether it was his own backyard or simply cigarette smoke. He had previously experienced the same thing at a cinema when, as he walked out, he was 'unusually conscious of the weight of his coat and of the weight of his feet upon the floor'.¹³ This is something like the 'presencing' associated with the right hemisphere, and with mindfulness, which is also independently associated with the right hemisphere. In the other case, no further details are given, so it might or might not count against the argument.

As to the opposite sense, a feeling of unreality, Mullan and Penfield mention 10 cases involving ‘strangeness, change or unreality’. Unfortunately, the unsystematic way in which the cases are reported makes it impossible to draw firm conclusions: on seven of the cases there are no details, and the authors do not distinguish adequately between feelings of unfamiliarity, or things being altered, on the one hand, and a sense of unreality as such, on the other. Two cases in which subjects felt ‘detached’ and that the world was ‘unreal’ involved excitation in the *left* hemisphere. The only other series that reports diminutions in the sense of reality associated with lateralised epileptic foci found that the majority were in the left hemisphere, which would support this interpretation.¹⁴ However, the data do not permit a clear-cut conclusion.

As we saw earlier, damage to the left hemisphere is markedly less likely to cause distortions of reality than damage to the right hemisphere, but it cannot be excluded from the picture altogether. The only two cases of left hemisphere lesions that involved more than a disturbance of visual angle in Cutting’s systematic review of almost 200 cases concerned what he calls a change in ‘emotional value’: in both cases left hemisphere impairment involved an increase in intensity of experience. In one of these cases, reported by Howard Cushing in 1922, there was an ‘exaggeration of his special sense impressions, i.e., flowers become extraordinarily beautiful, odours are intensified, his vision appears to be remarkably keen, so that objects seem to be increased in size’; this involved a glioma of the left temporal lobe and a consequent right-sided visual field defect.¹⁵ In the other case, reported by Macdonald Critchley in 1951, he states that the side of the lesion was unverified, although he thought it was more likely to be left-sided: during what sound clinically like complex partial seizures ‘one of the chessmen, his opponent’s knight ... for about half a minute seemed distorted – the pieces seemed to stand out more clearly, and the carving seemed deeper and more attractive.’¹⁶ Sadly, once again, we cannot be completely sure how to interpret these two cases; the first probably involves a release of the right hemisphere, the second an excitation of the left.

There are fortunately quite detailed first-hand accounts by individuals whose sense impressions were unusually vivid following left hemisphere damage. This is clearly described by Jill Bolte Taylor following her stroke; but also, for example, by a pilot, Stephen McKinnell, who also suffered a left hemisphere stroke, who found his visual perception abnormally clear:

I remember my attention to the tiny birds that were busy flitting among the dense dark green bushes in front of the car. It was like I was seeing them in a new light ... [And, on another occasion] I felt fantastic seeing the trees and the sunshine. Like my experience watching the birds, I felt that I was seeing them through different, more 'seeing' eyes.¹⁷

That would also accord with more recent cases of the converse phenomenon, *unreality* following *right* hemisphere lesions, such as a man with right posterior white matter tract disruption who reported that his surroundings did not 'feel real', which he attributed to a sense of emotional disconnectedness from his visual perceptions.¹⁸ And since, as we shall see, emotional connectedness is highly dependent on right hemisphere function, and the sense of reality on emotional connectedness, it seems reasonable to assume that left hemisphere damage might increase, and right hemisphere damage decrease, the sense of reality.

Worth including here is the phenomenon of *déjà vu*, as an anomalous experience of reality. Abnormal electrical activity in the right hemisphere should lead to an excess of the feeling of 'unique' familiarity – or its loss altogether, depending on whether the result is the exaggeration or diminution of the right hemisphere's characteristic mode of being. Yes, it's '*déjà vu* all over again': or its converse, *jamaïs vu*, 'never before seen'. And indeed both of these phenomena usually result from right hemisphere disturbance, rather than left – unless in left-handers.¹⁹ According to Cutting, there are 30 right-sided cases and seven left-sided cases in the literature to 2011.²⁰ If one includes cases of *déjà vécu* ('already experienced'), a similar phenomenon,²¹ the figure becomes 45 right-sided to seven left-sided.²² A study of 27 subjects revealed that '*déjà vu* episodes in patients began with polyspike activity in the right temporal lobe and, in some cases, ended with the slow-wave theta-delta activity in the right hemisphere'.²³ One man had the curious belief that he had lived the same part of his life over and over again (*identidem*): he had an epileptogenic focus in the right temporal lobe.²⁴ By contrast, one paper and a case report suggest a possible association between *déjà vu* and left temporal pathology.²⁵

There are more straightforward criteria of being in touch with reality. What can we say about the left hemisphere's capacity to understand the world in terms of its human content? Here, too, being less in touch with reality as it is perceived, less in touch with the body and the implicit, jumping to conclusions and being unable to shift mindset, is not a good start. But there are other, essential, factors in having a solid understanding of human reality which the left hemisphere seems not to 'get': the emotional import of human behaviour. Oliver Sacks writes that 'one cannot lie to an aphasiac'. Such a patient may not understand language, and so is not deceived by it, but instead 'grasps with infallible precision ... the total, spontaneous, involuntary expressiveness which can never be simulated or faked, as words alone can, too easily.'²⁶

In the film *The Divided Brain*, Jill Bolte Taylor even suggests that people with left hemisphere strokes should be employed as lie-detectors.

CONNECTING WITH OTHERS

We noted earlier the rather odd emotional state of Zingerle's patients – a striking detachment or lack of concern, which is typical of patients with right hemisphere dysfunction. Although it is true that the right hemisphere is far more involved than the left in emotional expressivity and receptivity – picking up other people's feelings and sympathising or empathising – it is absolutely not the case that the right hemisphere is 'emotional' and the left hemisphere 'cool' and rational. Anger, for example, an emotion not noted for its empathic nature, is one of the most strongly lateralised of all emotions, and it lateralises to the left.²⁷ Irritability and elation (when pathological, the cardinal signs of mania) are also more left- than right-lateralised, and associated with the left frontal pole, while sadness and melancholy (when pathological, associated with depression) seem to be associated with the right frontal pole, which is also the seat of empathy and social emotions.²⁸ A capacity for sadness is highly correlated with a capacity for empathy;²⁹ and conversely those who lack empathy, such as psychopaths, have difficulty recognising expressions of sadness in face or voice.³⁰ In turn, a capacity for sadness and empathy together is necessary in order to experience the socially vital feelings of guilt, shame and responsibility.³¹ People with right hemisphere damage tend to be impaired not just in emotional expression and interpretation, but may suffer a general loss of emotional depth.³² The eleventh-century Persian physician and polymath Avicenna (Ibn Sina) observed that melancholics have 'a multitude of wrinkles on the left side',³³ which may have been an astute observation that the left hemiface is more emotionally responsive and expressive, and that those who are more empathically engaged are more prone to melancholy.³⁴ Anger alone of emotions is more expressed in the right hemiface.³⁵

Some form of fellow-feeling in animals is ancient, and so is its association with the right hemisphere. Additionally we know that, when homing, pigeons fly so as to keep their favourite partners to the left, where they can be monitored by the right hemisphere, and pigeons observe visual cues from a given conspecific more closely with their left eye, and are more responsive to what is seen to their left.³⁶ By contrast, birds' *territorial*

behaviour is right eye (LH) dominated.³⁷ Similarly, male fish show more sexually motivated behaviour using their right eye (LH), females with the left eye (RH); and both generally more affiliative behaviour with their left eye (RH).³⁸ Bottlenose dolphins tend to stroke other dolphins more with their left flipper, and keep their preferred conspecifics to the left.³⁹ At the most primal level, the empathically connected right hemisphere prefers to keep what it guards to its left: creatures as various as whales,⁴⁰ walruses and flying foxes prefer to keep their young to the left of them,⁴¹ a tendency I have had occasion also to observe with ewes and their lambs.

The relationship between the two hemispheres is, as always, not symmetrical. Research in birds shows that the right hemisphere is generally ‘in control of behaviour’: the performance of normal chicks and experimentally induced left-eye-only (‘right hemisphere’) chicks is usually indistinguishable; not so in the case of right-eye-only (‘left hemisphere’) chicks.⁴²

Theory of mind

There is something which is misleadingly called ‘theory of mind’ (ToM) in the psychological literature – misleadingly, because it is not a theory, nor does it involve holding a theory, and concerns only one aspect of mind. It is the capacity to put yourself in someone else’s position, see what they see, and feel some of what they feel. Part of it is a matter of cognition – having the theoretical awareness that the contents of others’ minds differ from one’s own; and part is a matter of empathy – feeling one’s way into another’s mind. This is a huge topic with a commensurately large literature. In brief, it used to be thought that ToM was unique to human beings, and that even humans did not develop it till the age of about four (many people with autism never develop it, at least in the fullest sense). We now know that at least the cognitive aspect, and in many cases it may be much more than this, is present in animals as various as elephants, apes and dogs, whales and dolphins, crows and magpies, goats and seals, and that it is therefore much more widespread than we imagine.⁴³ It may also be that children develop at least a rudimentary form of ToM much earlier than we thought, by about 18 months or even earlier.⁴⁴

The classic test for ToM is called the Sally-Anne test.⁴⁵ Two dolls, Sally and Anne, are seen playing with a marble. When they finish playing, Sally puts the marble away in a basket, and leaves the room. Anne is then seen to remove the marble from the basket and put it in a box. The question is, ‘where will Sally look for the marble when she comes back?’ Normally we would say ‘in the basket’, because we know that that is where *she* thinks it is. Young children and those with autism reply ‘in the box’, because that is where *they* know it is.

There is a fascinating piece of research which is open to the interpretation that some right hemisphere damaged patients can’t tell the difference between the realm of thought and reality, and may even transpose them.⁴⁶ In the Sally-Anne test they answer like autistic subjects, indicating where they know the marble to be, not where Sally thinks it is. Then when asked where the ball *really* is, they switch – at precisely the wrong moment – to where Sally thinks it is. At the least it would be fair to say that they don’t have a firm grip on what another mind is thinking.

In general, empathy is highly dependent on right, especially right frontal, function.⁴⁷ Many recent studies suggest that the right hemisphere, specifically the right parietotemporal junction, is critically involved not only with empathising, and reorienting attention, but in attributing a belief to another person⁴⁸ – being able to tell what someone else is thinking; and in distinguishing agency– being able to tell who did what (see Plate 6[b]).⁴⁹ Where intention is not transparent and ‘might require reasoning [to] decipher it’, the right hemisphere plays a critical role.⁵⁰

Understanding the intentions of others is severely impaired in right hemisphere damage, as it often is also in autism and schizophrenia.⁵¹ The right ventromedial prefrontal cortex is dysfunctional in psychopaths, who do not have the usual feelings for others.⁵² What is called ‘cognitive empathy’ is disrupted by damage to the left cingulum,⁵³ but what, by contrast, is called ‘emotional empathy’ is diffusely served by the right hemisphere, with areas of particular significance within it, including the right frontal cortex,⁵⁴ the right temporoparietal region,⁵⁵ and the right uncinate fasciculus.⁵⁶ This bundle of nerve fibres, incidentally, is an important white matter ‘superhighway’ connecting the frontal with the temporal region, and is one of the last white matter tracts to mature in the brain (often in the 20s or even 30s).⁵⁷ This tract, and the other huge

integrative, white matter ‘superhighway’ of each hemisphere, the superior longitudinal fasciculus, is larger in the right hemisphere in normal subjects⁵⁸ (see Plate 2[a]). Its role in connecting emotional centres in the limbic system with the orbitofrontal cortex explains why abnormalities of structure and function in the tract have been implicated in psychopathy;⁵⁹ as well as in autism, where the right uncinate fasciculus has been found to be smaller than the left.⁶⁰ And, once again, abnormalities of both volume and myelination here and in other white matter tracts have also been implicated in schizophrenia.⁶¹

Empathy is not the result of solving a cognitive conundrum. Philosopher Matthew Ratcliffe argues that

interpersonal understanding is seldom, if ever, a matter of two people *assigning* intentional states to each other but emerges out of a context of interaction between them. Self and other form a coupled system rather than two wholly separate entities equipped with an internalised capacity to assign mental states to the other. This applies even in those instances where one might seem to adopt a ‘detached’ perspective towards others.⁶²

SOCIAL AND EMOTIONAL RESPONSIVENESS

The right hemisphere is the mediator of social and emotional behaviour.⁶³ People with right hemisphere damage may show a ‘blanket disregard’ for the feelings, needs and expectations of others.⁶⁴ As Allan Schore has demonstrated, the mutual gaze of mother and infant mediates, and is mediated by, the mother’s right orbitofrontal cortex engaging with that of her infant, and is critical for the development of a stable, secure individual, no longer fused with, but still deeply bonded with, the mother – a vital foundation for any coherent society of individuals, both mutually dependent and independent as they are.⁶⁵

Jean Decety and Thierry Chaminade, two leading neuroscientists of affect, write that ‘self-awareness, empathy, identification with others, and more generally inter-subjective processes, are largely dependent upon ... right hemisphere resources.’⁶⁶ If I imagine myself in pain, I use both hemispheres, but your pain is in my right hemisphere.⁶⁷

So-called ‘mirror neurones’ have become so topical that they have passed into popular culture, where there is a probably exaggerated idea of their significance. These are neurones that are active both in carrying out an action, and in watching another carry out an action. Clearly this is fascinating, because it suggests that we do literally experience some of what another is experiencing when we watch and empathise. Mirror neurones may lie behind the important capacity for imitation, which is an essential element in human evolution.⁶⁸ But it is likely that such mirroring qualities are a feature of many much broader networks in the brain, and may simply describe an aspect of the functioning of the nervous system in general, whereby it attunes to other nervous systems, rather than of a special region within it.

Both hemispheres have mirror neurones, but the system is in an important respect right-lateralised.⁶⁹ What makes the difference as to which hemisphere is involved is not just the location of an action in space, but more importantly its nature. When the action is instrumental, the left hemisphere is involved, but when it is non-instrumental, the primary contribution is from the right frontal and temporal regions.⁷⁰ For example, in reading and ‘mirroring’ the expression on another’s face, it is the mirror

neurones of the right pars opercularis, in the frontal lobe, that are primarily active (it is they, amongst others, that appear not to function in autism, though such mirroring defects are part of a bigger picture). Over and above differences in mirror neurones, there is a distinction between observing instrumental action – a hand reaching out to grasp, say, a glass – and the perception of signs conveyed by expressive, fluid motion, for example, sequences of dance-like, whole-body movements. The first activates the left temporoparietal region, and the second the right temporal and limbic region.⁷¹ In fact, viewing non-instrumental, biological motion is largely right hemisphere-dependent, regardless of whether it happens in the left or right field of vision.⁷² Kinaesthesia (awareness of the position and movement of the parts of the body) seems largely dependent on the right hemisphere as does perception of limb movement.⁷³

Simultaneous EEG monitoring of two subjects communicating, while ‘both participants are continuously active, each modifying their own actions in response to the continuously changing actions of their partner’ reveals synchronisation, at the millisecond level, of the right centroparietal and right temporoparietal regions in each subject.⁷⁴ They really do ‘resonate’.

Essentially, the left hemisphere is good at understanding the *what* of motor actions such as grasping a fork, picking up a cup, or flicking a switch, but not good at understanding the *why*. For that we need the right hemisphere, especially the right temporoparietal region. But this only begins to convey the hemisphere difference involved.

It sounds like a nice symmetrical division of labour: *what* in the left, versus *why* in the right. Indeed, in a split-brain patient, there was found to be a left hemisphere dominance for understanding *what* is done, and a right hemisphere dominance for understanding *why* an action is carried out.⁷⁵ These aspects of experience are not, however, of equal value. As the authors of one important paper in the area put it, ‘the simple action of pressing a switch has many possible interpretations – the actor could be turning on a light, deleting critical files from a computer, or even turning off a life-support system’.⁷⁶ Full marks to the left hemisphere for being able to work out that a switch is being pressed; but surely when we say understanding, we mean more than that. We in fact mean all that is hidden under the deceptively short word ‘why’ – the answer to which could be as long as a novel. Understanding, in this case, really means *understanding*; the mere *identification* of an action could, after all, be well enough performed by a

computer, without any understanding being involved. Understanding the motivations of an action means understanding what it is to be a living human being, and working out what makes sense in a context as wide as our lived experience – and it comes by virtue of the right hemisphere. This is not just a ‘stage’ in a serial process: it is something that begins at the start of understanding the *what* of the action, and is rapidly and reverberatively revisited by the right hemisphere over the time course of milliseconds, reassessing the situation, to the point where we ‘see’ what is going on. The right hemisphere areas involved ‘do not simply function as part of a serial, unidirectional network’ but are part of ‘a highly dynamic process’.⁷⁷

Children with autism recognise readily enough *what* another individual is doing,⁷⁸ but frequently fail to understand *why* the individual is doing it.⁷⁹ Reminiscent of Gazzaniga’s remark that ‘unlike the left hemisphere, the right hemisphere, in our view, places a premium on the truth’, is a comment by Julian Keenan and colleagues: ‘The right hemisphere, in fact, truly interprets the mental state not only of its own brain, but the brains (and minds) of others.’⁸⁰ More than that, in the words of Jaak Panksepp, an acknowledged authority on ‘affective neuroscience’ (the title of one of his best-known works), ‘in short, our left hemisphere – the one that typically speaks to others – may be more adept at lying and constructing a social masquerade ...’⁸¹

Emotional receptivity and expressivity

In general, a huge body of evidence confirms that the right hemisphere is much superior to the left in receiving, interpreting, recalling or understanding anything that involves emotion. This is pretty much the whole of the human realm (and more broadly the realm of the animate), especially the social realm – how we relate to one another; and there is an equivalently large literature supporting the superiority of the right hemisphere in all aspects of social perception. The superiority of the right hemisphere extends to the emotional aspects of verbal language, and a general capacity for emotional memory, as much as to body language or the language of the human face.⁸² Behavioural evidence in normal subjects, lesion data and neuroimaging studies ‘strongly support’ the idea that face processing depends more on the right hemisphere, as does eye gaze

perception.⁸³ A large body of studies documents that unconscious ‘processing’ of emotional ‘information’ goes on mainly in subcortical regions of the right hemisphere, and that unconscious emotional memories are stored in the right hemisphere.⁸⁴ Participants in a theatre or film-showing prefer to have the main part of the scene relayed to their (left visual field) right hemisphere.⁸⁵ A study of 37 patients with focal brain damage revealed no impairments in recognising any emotion in subjects where the lesion was limited to the left hemisphere.⁸⁶

Human voice perception is strongly lateralised to the right hemisphere in all respects.⁸⁷ Discrimination of the naturalness of the voice, the sex and the identity of the speaker, especially involve the right superior temporal sulcus and a neighbouring region, the precuneus.⁸⁸ Scanning studies demonstrate that the right temporal lobe and right inferior prefrontal cortex are the primary areas involved in emotional prosody (tone of voice),⁸⁹ evidence supported by cases of brain-lesioned patients with a deficit in speaker discrimination or recognition.⁹⁰ One reason that schizophrenic subjects may not pick up on prosody is that they exhibit (as do bipolar patients) left lateralisation of the normal right-lateralised temporal lobe response to emotional prosody.⁹¹

There is a rightward asymmetry of cortical involvement in laughter – both its production and perception – confirmed by meta-analysis.⁹² Furthermore, the reception of non-verbal human sounds, including laughing, but also crying and shrieking, are strongly lateralised to the right hemisphere.⁹³

Although there is a theory espoused by Richard Davidson that the left hemisphere processes positive and ‘approach’ emotions and the right hemisphere negative and ‘withdrawal’ emotions, I have explained elsewhere why this is not convincing.⁹⁴ This does not explain why repellent odours have been repeatedly found to activate the left hemisphere, pleasant ones the right hemisphere.⁹⁵ Indeed, more direct evidence shows specifically that greater relative right hemispheric activation has been found to be related to approach, rather than avoidance motivation;⁹⁶ that activation of the left temporal cortex increases the susceptibility to experience negative emotions;⁹⁷ and that the effects of cortical stimulation on experienced emotion provide ‘clear evidence for left lateralisation of negatively valenced effects’ and ‘strong right lateralisation of neutral

effects', which is quite the opposite of what the valency model would predict.⁹⁸

An alternative theory is that the right hemisphere is dominant for all forms of emotional receptivity and expressivity, although it appears that the left hemisphere is particularly specialised in dealing with the expression of anger and disgust. A right hemisphere bias for the production and perception of emotional expressions appears to be (with the above exceptions) independent of valence.⁹⁹ Guido Gainotti, who has repeatedly reviewed the literature, writes that 'the great majority of studies conducted both on normal subjects and with brain-damaged patients have supported the "right hemisphere dominance" hypothesis' – ie, that the valence of the emotion is not the critical factor.¹⁰⁰ One piece of research both confirmed the right hemisphere dominance hypothesis and specifically contradicted the approach/avoidance hypothesis at the same time:

all emotions showed significant lateralisation to the right hemisphere; however, differences in strength of lateralisation within the right hemisphere were found. Stronger patterns of right hemisphere lateralisation were found for positive emotions and for emotions of higher intensity.¹⁰¹

Further, a more recent study of patients with damage to the right inferior parietal cortex 'did not support the hypothesis about division of labour between hemispheres based on the emotional valence'. It found that the 'dominant mood in [right hemisphere-lesioned] patients is a neutral placidity; sometimes it is interrupted by bursts of irritated aggression, but there are no episodes of worries, fear or vivid happiness'.¹⁰² Such subjects are often quite out of touch with their own emotions, and can't be expected to report them correctly: one patient, in a state of 'intense irritation' and 'just after two aggressive attacks' directed at his mother sitting nearby,

selected as a descriptor of his state the photo of a boy whose smiling face almost 'radiated' happiness. After a long search for an appropriate photo, another patient said: 'No, there is no such photo here as I do not feel anything.'

This is part of the picture of lack of awareness of the body. These patients seemed to have no awareness of fatigue or pain. One who was 'obviously exhausted' denied fatigue; another said he could never understand what it meant 'to be fatigued'. 'Should I have some pains?', he continued. 'But I have no pains, nowhere.'¹⁰³ Yet another study found that a right hemisphere-damaged patient 'did not have a proper notion of what a facial expression of happiness looks like, and could not adequately apply this label', and concluded that 'the proper recognition of both negative and positive facial expressions relies on the right hemisphere, and that the left hemisphere produces a default state resulting in a bias towards evaluating expressions as happy', even if they clearly are not.¹⁰⁴ This is in keeping with its tendency to fatuous optimism.

Stephen McKinnell noticed after his left hemisphere stroke that he was much better at reading faces, and that he and other similar patients could communicate insights between one another without speaking.¹⁰⁵ The highly articulate self-report of a patient ('Professor F') who had a left frontoparietal stroke revealed an increase in his capacity for emotional depth. His wife described him as, prior to the stroke, having 'a rather rational attitude toward life'. After the stroke he described the opening of a new 'emotional dimension', from which he 'relates to himself and to the world':

I thank the accident because deep down I start to perceive in myself, to perceive from reality, things that I did not perceive before. I mean, ways of relating, of being with myself, ways that I did not have before. This has been the strongest change ... to be now beginning to grasp the emotional thing, the emotional dimension in me ... Emotions were hidden by rationality ... Happy feelings ... the accident did not reduce them, but on the contrary, it augmented them. The capacity to feel moved, the capacity to cry ... and this is part of my life. The accident made me more sensitive to that.

In the case of positive emotions ('I am certainly happier than before', he says), this seems to generate feelings of well-being and satisfaction, as well as to facilitate the capacity to empathise with other people's happiness. Yet he also feels sadness with greater intensity:

especially in relation to sadness ... the intensity pulls me to be sadder than I am ... For example, there are times when I have been sad and I do not know why ...

His objectively assessed ability to understand and interpret emotions was intact with the single marked exception, interestingly enough (given his left hemisphere lesion), of disgust.¹⁰⁶

I would like to propose an alternative theory, closer to the theory of right hemisphere dominance for all emotions, but with a refinement. What is striking is that anger, irritability and disgust stand out as the exceptions to right hemisphere dominance, fairly dependably lateralising to the left hemisphere. That is, of course, in keeping with the concept that the right hemisphere is required for emotional *depth*, which I would argue is certainly part of the picture. But the other part is that, in keeping with everything else we know about hemisphere differences, the right hemisphere is engaged in social bonding and empathy, the left hemisphere in social rivalry and self-regard. This explains the clear relation between sadness and the capacity for empathy, guilt and compassion, all of which appear to be associated with predominance of the right frontal pole; and elation with irritability, anger, insensitivity and exuberant self-confidence, all of which appear to be associated with predominance of the left frontal pole. Terms such as ‘positive’ and ‘negative’ (in what sense?), ‘approach’ and ‘withdrawal’ (to what end?), are blunt instruments and should be retired.¹⁰⁷

It is principally the right hemisphere that enables us not only to identify and remember individual faces, but also to understand their expressions. We have seen that the inability to recognise faces, called prosopagnosia, suggests right hemisphere damage: in classic cases, the face lacks depth and is flattened like a plate, with a few large features. In one sense, it is a problem of relating the parts to the whole. Relying on the left hemisphere alone, we are reduced to relying on the obtrusive parts – a nose, say, or, in the case of Sacks’s Dr P, his wife’s hat – not on the configuration of the face in its entirety.¹⁰⁸

Human beings use primarily the right hemisphere for perceiving facially expressed emotions: ‘right hemisphere dominance in face perception and individual recognition ... is, in fact, one of the more notorious lateralization effects in our species.’¹⁰⁹ But not just in our species.¹¹⁰ This results in what

is known as the left-gaze bias (note that this is facilitated by rightward, not leftward, turning of the head), whereby the right hemisphere of the perceiving subject is preferentially brought into play. A study comparing the left-gaze bias in humans and in laboratory-raised rhesus monkeys found important similarities – and differences.¹¹¹ Interestingly, in humans a clear left-gaze bias was found only when looking at human faces, whereas monkeys showed a clear left-gaze bias for both human and monkey faces. A subsequent fMRI study demonstrated a more pronounced activation of the right superior temporal sulcus in macaque monkeys,¹¹² and the same advantage to the right hemisphere in face recognition, as in humans, has also been found in split-brain monkeys.¹¹³ Appropriate eye contact is controlled largely by the right hemisphere.¹¹⁴ Mutually shared gaze, the interpretation of the face and the voice, in terms of all that each communicates implicitly, as well as its age and sex if unfamiliar, and its identity if familiar, are all highly dependent on the right hemisphere, as is olfactory perception of body odours and pheromones.¹¹⁵ The same is true of biological motion perception, as we have seen.¹¹⁶ A review of social perception in three modalities – visual, auditory and olfactory – concludes that ‘in all of the three modalities considered, the assignment of a dominant role to the right hemisphere in social perception would appear well deserved.’¹¹⁷ The right hemisphere specialises in the interpretation of facial expression and body language.¹¹⁸ Moreover the right temporal region appears to have areas not only specific for living things, but additionally for all that is specifically human; and this is distinct from its advantage in reading human faces.¹¹⁹

So much for receptivity. How about expressivity?

The picture here is similar: right hemisphere-damaged subjects show diminished expressivity in, as well as receptivity to, facial expressions, vocal prosody (expressive and receptive understanding of intonation) and body gestures.¹²⁰ It is the right hemisphere that is far more capable of expression, whether this be through the voice, body or face. Since the right hemisphere has greater control over the left half of the face, in general it is the left hemiface that is more expressive.¹²¹

This almost certainly lies behind the well-attested finding that portraits tend to show the sitter looking to the painter’s left, thus exposing their more expressive left hemiface to the viewer and situating the most expressive part

of the face in the left visual field – where it is optimally positioned to engage the attention of the right hemisphere. (In *The Master and his Emissary* I discuss research which shows how this tendency has co-varied with other emotionally sensitive factors over the course of Western civilisation.)¹²² This may also lie behind the marked preference in all human cultures going back thousands of years for representations of mothers with their babies cradling the infant to the left.¹²³ This representation accords with reality, and even left-handed mothers show the same tendency.¹²⁴ (Incidentally, adults prefer paintings in which the Madonna is holding the Child to her left.)¹²⁵ This pose exposes the mother's more expressive left hemiface to the infant, and the infant's more expressive left hemiface to the gaze of the mother. As one might expect, the great apes show similar tendencies for the right hemisphere to be more capable of emotional expression and understanding, and they, too, tend to cradle their infants to the left.¹²⁶

The key areas in inhibiting reflex responses, and in making the decision to take a certain course of action rather than respond automatically, are 'highly lateralised' to the right frontal cortex.¹²⁷ Subjects with right hemisphere damage exhibit a sort of devitalisation: they are more passive and lack initiative.¹²⁸ They also exhibit an emotional flatness, as we have seen, and this is inextricably linked to an inability to interpret social and emotional clues in context. A picture of a wedding gets to be interpreted as a funeral, since 'the woman is wearing a veil and several people in the picture are crying'.¹²⁹ In the cartoon-like drawings below, subjects with left hemisphere or right hemisphere damage were compared with normal controls on their capacity to generate appropriate content for the speech- or thought- bubble.¹³⁰ The left hemisphere deficit (LHD) group did not differ significantly from normal subjects, but the right hemisphere deficit (RHD) group produced responses that were verbose, missed the point, were inappropriate and had an oddly utilitarian slant. Examples:

Fig. 17. 'You may now kiss the bride': impaired emotional and social understanding in right hemisphere dysfunction (from Baldo, Kacinik, Moncrief et al 2016)

a) *Normal*: 'About that assignment.'

RHD: 'OK lady. What kind of shoes did you buy?' / 'Nice shoes.' / 'Uh really honey – I didn't mean to pee on the couch.'

b) *Normal*: 'Boy, she's cute.'

RHD: 'I wonder how big her allowance is.' / 'Let's arm-wrestle.'

c) *Normal*: 'I now pronounce you man and wife.'

RHD: 'Nice to meet your bride.' / 'I now pronounce you man and wife. Or, as a licensed gynaecologist, you may need my services.'

d) *Normal*: 'This is our proudest day.'

RHD: 'Now, my boy, you're a college graduate. Now you're out to meet the world. Go out and learn how to make a dollar.' / 'Will you be paying back your loans soon, honey?' / 'Congratulations. You finally graduated. May you make your mark in your business life now.'

Given what we know about the left hemisphere's relatively limited capacity to understand human motivation and feeling, it is once again not

surprising that narrative forms of thought are associated with the right hemisphere.¹³¹ Narrative is too complex, multifaceted and involved with understanding the business of life for the left hemisphere to understand.¹³² If asked a straightforward question about their current circumstances, people with right hemisphere damage seem unable to provide the structure or overview required to answer it:

They wended their way through a maze of disassociated detail, seemingly incapable of filtering out unnecessary information. Although they had at their disposal all the components of a narrative, they could not actually assemble them into a narrative.¹³³

Right hemisphere-injured individuals have severe difficulty making the correct inferences.¹³⁴ It is the right hemisphere that understands the emotional or the humorous aspect of a narrative;¹³⁵ it is also better able to appreciate irony and sarcasm – all that is not explicit but radically alters meaning.¹³⁶ There is a large literature showing that the right hemisphere is crucial for appreciation of cartoons, jokes and humour of every kind, and that damage to the right hemisphere impairs all forms of humour comprehension and generation.¹³⁷ In fact, right hemisphere-damaged patients find it hard to tell the difference between jokes and lies – neither of which, after all, are factually correct.¹³⁸ The right hemisphere alone can infer the overall meaning of both conversation and narratives;¹³⁹ and it is the right hemisphere that makes judgments about the truth or plausibility of these narratives, either as regards story elements,¹⁴⁰ or as a whole.¹⁴¹ Right hemisphere damage leads to difficulty in understanding or deriving the theme of a story, organising sentences into stories, recalling connexions between story elements, and above all in getting the ‘gist’.¹⁴² It also leads to problems understanding non-literal meaning, eg, metaphor;¹⁴³ and figurative language, which is common in narratives of all kinds, places particular demands on semantic integration, which requires the right temporal cortex to be intact.¹⁴⁴ Even just mentally rearranging words into a sentence is impaired in right hemisphere damage.¹⁴⁵

The early twentieth-century German neurologist Walther Poppelreuter described how his patient, Robert Spyrä, a 22 year-old musketeer with right

posterior shrapnel injury, in describing a film, ‘reports a large number of correctly observed individual scenes without any grasp of the overall plot structure’.¹⁴⁶ He has literally lost the plot. If the isolated left hemisphere of a split-brain patient tries to re-tell a narrative, it lacks concreteness and specificity in its relation of the story, and becomes abstract and generic; and it gets time sequences wrong, conflating episodes that are separate in the story because they look similar (in other words, it categorises them, and therefore puts them together, even though in the lived world their meaning is destroyed by being taken out of narrative sequence). In place of a narrative, it produces a highly abstract and disjointed meta-narrative.¹⁴⁷ Once again there is a loss of living *flow*.

In a now classic study, RHD and LHD patients were compared with normal controls in constructing a coherent story, retelling a narrative, drawing inferences from behaviour in a story and selecting appropriate punchlines for a joke.¹⁴⁸ The authors comment that, amongst other things, ‘the language of [RHD] patients is often excessive and rambling; their comments are often off-colour and their humour frequently inappropriate; they tend to focus on insignificant details or make tangential remarks; and the usual range of intonation is frequently lacking.’ In this study, the LHD group performed as well as normal subjects, but the RHD group had grave difficulty. Asked to say why a man in one story acted in a certain way, only 22% of the RHD patients’ responses were correct, while the LHD patients were 90% correct (better than the normal groups’ responses, which were 80% correct).

In retelling stories, the RHD patients produced an ‘abundance of embellishments (ie, extraneous or unnecessary comments or additions to the story)’. One patient confabulated that the robber in one story had stolen all of the grocer’s groceries (instead of his money) and that, as he was escaping, he ‘tripped on a bad sidewalk, fell down, and broke all the eggs’.¹⁴⁹ Another, after finishing his retelling, pointed to the experimenter and added, ‘They called her mother, and said you were there’.¹⁵⁰ Subjects frequently and incongruously *disputed* elements in the stories, as if they misunderstood the nature of fiction. The authors comment:

These frequent intrusions suggested that, rather than respecting the story as a separate fictive entity, patients allowed personal memories

and associations, differences of opinions, and asides to surface as part of the story. Constantly violating the boundary of the stories, the patients seemed uncertain about the difference between what could happen and what actually did happen.

Once more we see the left hemisphere's difficulty in telling fantasy from reality, theory from fact. Similarly, while the subjects chose largely irrelevant punchlines to jokes, 'as in the story retelling task their reactions were serious and critical. One patient said (with respect to the final, funny frame), "The first thing I'd like to know is how the elephant got up that tree". Clearly this patient was unable to accept the "cartoon" world as different from the "real" world.'

The emotional repertoire of the RHD patients is severely limited and – yes, a little 'off-colour'. A story about a fire contained information such as the 'little girl began crying; her heart pounded as she crept in'. One patient, asked about the emotions experienced by the girl, replied that she 'didn't express any opinion or feelings except being excited. She didn't wet her panties, she didn't kiss anybody around ... and she didn't hug anybody.'

And, as usual, when the left hemisphere doesn't understand, it doesn't seem to be aware of the fact:

it should be stressed that the right-hemisphere [deficit] patients virtually never respond 'I don't know' to an open-ended question. Instead, they generally contrive an answer – confabulating if necessary – in seeming indifference to the inappropriateness of the response.

The speech of those with right hemisphere damage has been described by Penelope Myers of the Mayo Clinic as 'copious and inappropriate ... confabulatory, irrelevant, literal, and occasionally bizarre.'¹⁵¹

It is part of my thesis that the different aspects of right hemisphere dysfunction are not by any means a more or less random assortment, but a coherent reflection of a single, broad but cohesive, underlying change in the experienced nature of reality. So in a paper on constructional apraxia – the inability, almost always following right hemisphere damage, to copy, or draw from memory, a simple visual image – the authors write: 'These

patients' inability to give an overview or extract a moral from a story, to assess humorous material, to appreciate fully the significance of their disabilities, or to assess properly social situations would all seem to reflect a breakdown in normal contextual evaluation or conative awareness [awareness of the 'point']. Even constructional apraxia might be seen along these lines. Here, too, right brain-damaged subjects failed to appreciate the relationship of component objects or elements to the overall form or task, *and, in so doing, are seldom aware of their impairments and are rarely affronted or upset when corrected.*'¹⁵²

Reports of adult patients who have undergone a right hemispherectomy convey a similar picture: shallow affect, rigidity, lack of imagination. 'Together with emotional experience most of their personality vanishes as well.'¹⁵³ According to one review of patients with right hemispherectomy, 'it is in the higher and more complex integrations involving insight, emotional control, initiative, constructive ideation, and imagination that hemispherectomy takes its toll'.¹⁵⁴ One patient 'was occasionally maudlin and abnormally elated' and 'was inclined to repeat herself without being aware of it'. In another case (though he was left-handed), 'there was paucity of associations, stereotypy and some perseveration [inappropriate repetition from one context to another] of ideas ... a superficial mentation with little originality, lacking in any deep introversive processes and in motivation, and given to sudden and illogical mood swings and easy petulance.' In a different review and case report, another patient was said to exhibit 'paucity of associations, perseveration and stereotypy, concreteness of thinking, and delayed reaction times.'¹⁵⁵ Another was 'superficially smart and clever in repartee', but 'emotionally unstable, inconsistent and lacking in perseverance'. And yet another 'gave a minimum number of responses [on the Rorschach test], fatigued easily, displayed a narrow range of associations and little originality or imagination, indicating a dull intellectual functioning, and no ability for deep thinking or for adequate self-evaluation. The affect was that of a rather shallow irritability.'¹⁵⁶

Patients with right parietal damage not infrequently report (as do some schizophrenic subjects) having 'no thoughts'. An external stimulus was required 'to launch the thinking process'. But they do not seem to complain about the lack of thought. This 'emptiness of mental life' appears to go hand in hand with the loss of personal and emotional memory:

Though patients' performance in ordinary memory tests could be nearly perfect, we learned about salient autobiographical events of their lives almost exclusively from relatives ... Even photos of an event were of little help: only formal knowledge such as names of participating persons and general circumstances was retrieved but nothing that was mediated by subjective experience.

And this extended to the subjective experiences of other people, even when the people were correctly recognised in a photograph.¹⁵⁷

Patients with damage to the right inferior parietal cortex avoid eye contact like autistic subjects, and even 'speaking to such a patient on the telephone, you never know for sure whether he/she is interested in a conversation or will hang up the next moment.' This is partly because their voice lacks life, is monotonous and has no emotional expression. Reciprocally, 'if one reads to the patient the same phrase with three intonations, that of doubt, mockery or fright, he/she will be unable to distinguish the variants by hearing.'¹⁵⁸

The face loses its liveliness, gesture is impoverished or stilted, and the gaze seems to be 'frozen'. Facial reactions do not disappear completely but, for example, a smile may have 'an unnatural, torturous character'. Often patients cannot recognise themselves in old photos.

Though socially inept, their formal knowledge and 'cognitive operations on information about inanimate objects' is intact, but only in 'the domain of thinking in which it is possible to ignore subjectivity: feelings, beliefs and intentions.' There are frequent social misunderstandings. By contrast, although left hemisphere damage frequently causes severe speech disturbances, 'we can understand almost everything that [such patients] wish to say or to ask, can feel their mood and often maintain a rather informative dialogue thanks to their intact facial expression, gesture and intonation.'¹⁵⁹

The left hemisphere is better able to inhibit the right hemisphere than the right is to inhibit the left.¹⁶⁰ In normal subjects, this is largely mediated by transcallosal pathways. But even without them, the left hemisphere remains 'dominant'. When, following callosotomy, there is intermanual conflict, it is always the left hand that is experienced as 'mischievous' or 'rebellious', because, although it may have superior insight, the right hemisphere's actions do not fit the left hemisphere's script. After a few

months, in most cases, split-brain subjects settle down and the intermanual conflict subsides: 'normal services are resumed', with the left hemisphere back in control. Dahlia Zaidel, who has researched with split-brain subjects for decades, writes that 'there are several sources of evidence that suggest that one hemisphere controls ordinary behaviour in split-brain patients, namely, the left hemisphere'. And she continues, 'indeed, what components are missing in verbal conversation or in nonverbal behavior are very likely those components which normally are contributed by the right hemisphere'.¹⁶¹ The emissary adopts the role of the Master.

Sperry's description of split-brain subjects is remarkably similar to the descriptions of right hemisphere deficit patients: 'Perseverance in tasks that are mentally taxing remains low in most of the commissurotomy patients, as does the ability to grasp broad, long-term, or distant implications of a situation ... their conversation tends to be restricted mainly to what is immediate and simple. Undue repetition of the same information or anecdote is common. There are indications of a tendency to fantasise, and a mild logorrhoea [excessive wordiness] seems to be present in some cases.'¹⁶² Klaus Hoppe reports of his impressions of the speaking left hemispheres of these patients after commissurotomy, that there is a paucity of dreams, fantasies, and symbols. The fantasies they have are unimaginative, utilitarian, and literalistic, their style discursive, and their themes circumscribed and rigid.¹⁶³

But it is the impact on emotion that is most striking. A split-brain patient, who had just heard that his mother had a severe illness and would shortly die, told the investigators that 'something funny' had happened – his voice, his words, his manner betrayed no hint of sadness, but rather he seemed jokey in a way that seemed incongruous to the onlooker.¹⁶⁴ Somehow his self-expression was cut off from its roots in emotional connectivity. A comparison of partially, with totally, commissurotomed patients revealed that the former used many more 'affect-laden' terms, whereas the fully commissurotomed patients exhibited more interest in detail than in feelings, and a tendency to use inappropriate words to describe emotions.¹⁶⁵ 'Hardly ever, if at all', writes Dahlia Zaidel, 'did I observe a sad facial expression, for instance. But I did observe facial expressions denoting disgust or dissatisfaction (with food, say, or with unusually long waiting periods).'¹⁶⁶

Stuart Dimond reports that in all the split-brain patients studied,

speech somehow appears to lack the quality of an essential interaction. The generative productive capacity is present but the speech emitted is often devoid of genuine interaction with the situation. This feature is difficult to describe. It is *as if a radio had been switched on*. Speech is produced but it is somehow mechanical and unempathic.¹⁶⁷

Literalism

Clearly the left hemisphere has difficulty understanding what one might call human meaning. Its attempts to understand are mechanical and literalistic.

What do we mean by meaning? If it means anything, meaning must surely go beyond rule-following (merely putting together a grammar book with a lexicon) and on into the heart of messy human experience. The words ‘mean’, ‘mind’ and ‘memory’ share common roots, so any account of meaning that does not begin in the raw stuff of human consciousness is off to a poor start. The left hemisphere on its own puts words together using often complex syntax and makes a kind of sense of them. But the real meaning of the communication, something called ‘pragmatics’, may escape it, as it would escape a computer. For example, if I say, ‘it’s hot in here today’, you understand, using your right hemisphere, that I mean ‘would you please open a window?’ Meanwhile your left hemisphere, if left to itself, notes with some puzzlement this supply of unasked for meteorological information.

Since the right hemisphere is involved in making sense of an utterance as a whole, it is recruited when we have to generate, rather than just read, the last word of a sentence – for which we have to understand not just language rules, but real-world meaning.¹⁶⁸ The right hemisphere is more sensitive than the left when it comes to discriminating unfamiliar *meaningful* from unfamiliar *meaningless* expressions.¹⁶⁹ (In fact, lexical semantics is crucial for the right hemisphere involvement in metaphor processing, in order to discriminate metaphor from nonsense.)¹⁷⁰ Semantic categorisation of usual words depends on Wernicke’s area of the left hemisphere; when the words are atypical, their semantic categorisation depends on the right hemisphere homologue of Wernicke’s area.¹⁷¹ Again,

when the words are unclear, partial or degraded, so that they can be understood only in context, the right hemisphere is of critical importance.¹⁷² And when the left hemisphere makes a mistake in contextual understanding, the interpretation is taken over by the right hemisphere.¹⁷³ In general, the right hemisphere becomes more involved as complexity of contextual understanding increases;¹⁷⁴ indeed the harder it is, in general, to interpret a sentence, for whatever reason, the more the right hemisphere homologues of left hemisphere language areas are recruited.¹⁷⁵ By contrast the left hemisphere positively *disengages* when the meaning is metaphorical or unfamiliar.¹⁷⁶

In a study of idiom comprehension, subjects were given a sentence such as ‘For weeks he hesitated to show the account books to the boss, but finally he decided he had to go in and just face the music’.

Fig. 18: Literalistic versus metaphorical thinking (from Myers & Linebaugh 1981)

There were equal numbers of subjects with right hemisphere brain damage, left hemisphere brain damage and normal controls. Their task was to choose between five pictures, only one of which showed the correct context and the correct, non-literal, meaning: two showed a literal meaning. Don't forget that people with left hemisphere damage are generally at a handicap when it comes to language, many being unable to speak, and some having difficulty understanding written or spoken language. Despite that fact, left brain-damaged subjects, relying on their right hemisphere, scored 87% correct (normal subjects scored 97%); but right brain-damaged patients, with supposedly intact language skills, scored only 27% correct.

The left hemisphere-damaged chose a literal interpretation only 3% of the time, as did normal subjects: the right hemisphere-damaged, however, relying on their left hemisphere, chose a literal meaning a remarkable 57% of the time.¹⁷⁷

One patient with a resection of a large part of his right hemisphere, when asked six weeks after the operation, 'Al, how do you feel?', replied, without a trace of irony or humour, indeed 'without any change in voice, tone or facial expression': 'With my hands'.¹⁷⁸

Back in 1973, Howard Gardner and & Gianfranco Denes had tested the ability of aphasics (subjects with loss of speech, almost always due to left brain damage) to understand both the denotative and connotative meanings of words.¹⁷⁹ They happened incidentally to include a group of six right hemisphere-damaged subjects, along with normal subjects, to act as controls, not expecting (back in those days) to find any problems with their language comprehension. However, as Gardner & Denes discovered, they had been wrong. When asked to take the connotation part of the test, all six with right hemisphere damage voiced objections, and two of them refused outright to take it; a third could not complete it. The three who did complete it did worse than some of those who were actually aphasic, although the numbers were too small to achieve statistical significance.

However, in 1984 Gardner and colleagues returned to the topic, looking at a group of 30 subjects (10 with right hemisphere damage, 10 with left hemisphere damage and 10 normal controls), and produced significant results.¹⁸⁰ In one part of the test subjects were given the words *lion*, *hawk*, and *canary*, and asked which two were more closely related. Either you choose to emphasise membership of the avian category, grouping hawk and canary together; or you choose to emphasise connotative, non-literal meaning, putting hawk and lion together as arch-predators. Another example was *deep*, *shallow*, and *wise* – you could take deep literally and emphasise the pair of opposites *deep-shallow*, or metaphorically and emphasise the metaphorical similarity *deep-wise*. As the researchers comment, 'in order to make this kind of choice, the subject must presumably ignore some components of meaning and focus on others'. What they found was that right hemisphere-damaged patients, relying on their left hemisphere, preferred denotative meanings; left hemisphere-damaged patients, relying on their right hemisphere, preferred connotative ones. Normal controls used both equally. These results were consonant with

other earlier work showing that left hemisphere-damaged patients, relying on their right hemisphere, preferred connotative meanings, grouping *tiger* and *shark* together because of their ferocity, rather than taxonomically grouping *shark* with *trout* as both types of fish.¹⁸¹

The right hemisphere therefore plays an important part in the understanding of all linguistic utterance – but, nonetheless, does not favour language as a way of expressing its perceptions of the world. Music is the primordial form of expression in the right hemisphere.¹⁸²

I have remarked that one of the most significant differences between the approach of the two hemispheres to language is that it is the right hemisphere that is best able to understand metaphor.¹⁸³ While the literature is for the most part very clear that the right hemisphere is principally involved, there are a few dissenting papers – which in itself is not surprising in science. I believe, however, that, since this issue ramifies into much of what I shall have to say about hemisphere difference throughout the book, the area could benefit from some clarification; and I'd like to take a closer look at the evidence at this point. (Those who are not particularly interested in the detail may want to move on a few paragraphs.)¹⁸⁴

Three issues tend to confound the picture here. The first is simply a failure to be clear about what one is examining. The second is a matter of methodology. And the third is epistemological: how we go about understanding metaphor – by breaking it up into parts, or by seeing it as itself part of a much bigger phenomenon? Let me take each in turn.

First, what counts as a metaphor in terms of our *experience*? Although all language may be in origin metaphorical, many of the metaphors are now dead: in other words, there is no felt gap between the use we make of each such word in daily life and the anchor in embodied reality from which it derives its meaning. Thus although it is, I hope, interesting to be aware that, for example, 'immaterial' is rooted in metaphor, we do not register the word any longer as metaphorical when using it. In calling something immaterial, I don't think and feel – and I don't suppose you do – that someone here's motherless. The word has lost 'depth', become one-dimensional. Literal.

Clichés are definitely better processed by the left hemisphere.¹⁸⁵ Thus there is not just a distinction to be made, but a polar opposition, between a fresh metaphor that still works as a metaphor, and a clichéd metaphor which no longer does. A poem cannot be composed of clichés, nor can the idea behind a joke be stale, if it is still to be funny. Distinguishing between true

metaphor and cliché is of paramount importance: according to my understanding of hemisphere difference, the live metaphor should be appreciated by the right hemisphere, while the dead metaphor, the well-worn idea, should be available to the unaided left hemisphere. This distinction has not always been carefully enough made when the brain correlates of metaphorical understanding have been investigated. Success in determining the localisation of metaphor comprehension depends on using familiar *versus* unfamiliar, or conventional *versus* unconventional, metaphors as discriminatory: and some researchers have indeed used such a paradigm.¹⁸⁶ Researchers using only highly conventional metaphors have, as might be expected, tended to find little evidence of right hemisphere involvement in ‘metaphor’ processing.¹⁸⁷ But when the metaphor is new or imaginatively demanding, the kind encountered in poetry rather than cliché, the right hemisphere is clearly involved.¹⁸⁸

Thus poetic phrases, such as ‘rain clouds are pregnant ghosts’, are understood by the right hemisphere, while clichés, such as, ‘babies are angels’, are understood by the left hemisphere.¹⁸⁹ And though familiar expressions activate the left hemisphere, whereas unfamiliar ones activate the right hemisphere, it is not just the novelty effect, but specifically the combination of novelty with metaphorical content, that appears to engage the right hemisphere.¹⁹⁰

The left hemisphere’s affinity is for what is explicit and familiar, the cliché. However, if we were suddenly to see the *literal* – not the metaphorical – meaning of the hackneyed phrase, that would refresh it and make it new: it would be a sort of metaphor in reverse, requiring insight, like seeing a joke. In fact the comedian Milton Jones makes a career out of such insights into metaphor, generating such one-liner gems as: ‘When my dad was nearing the end, he asked us to rub his back with lard – after that he went downhill fast’. In such cases the literal meaning (‘went downhill’) becomes the non-salient (unfamiliar, because non-clichéd) meaning, which accordingly should get to be processed in the right hemisphere. And the evidence confirms exactly this.¹⁹¹

Second, what about methodology? This is something I deal with in Appendix 1, so I will pass over it briefly here. The main point is this. An area of activity in one hemisphere may be limited in extent and significance, but *persistent* over the time period of a scan. Activity in the other hemisphere, though much more significant, may cover a larger area

(remember that complexity leads to wider activation) – the precise area of maximum activity, however, constantly *varying*. Under these circumstances, over the three to five second time period of the scan, the former will falsely appear much more strongly correlated with the activity than the latter. This becomes especially true when the results from numerous studies are aggregated, in an attempt to locate the ‘key’ area.¹⁹² This point is well made by one of the best meta-analyses of imaging studies on metaphor to date.¹⁹³ Adjusting for this effect brought the researchers’ findings ‘in line’, as they put it, with results from other types of study, showing right hemisphere involvement to be of fundamental importance.

According to the authors of another, almost contemporaneous, meta-analysis, this problem is also the likely explanation of one of their results: although around 130 of the points of maximal activity were in the right hemisphere, only *two* activated clusters came up in the analysis.¹⁹⁴ And, if one needed one, a third meta-analysis, which as far as I am aware did *not* allow for this effect, nonetheless concluded that involvement of the right hemisphere in processing metaphoric phrases is proportional to the degree that they are (a) not ‘conventional’, or (b) complex, or require (c) appreciation of context in order to be understood.

This study made a further important point about the interpretation of imaging: that it is not just an area’s activation that matters, but the extent of the increase in activation from baseline (eg, a change from 50–600, or even 500–600, may be more significant than one from 1,500 to 1,600). Contrasting metaphor processing with baseline, and with literal processing, in this study confirms the importance of right frontal areas and the right superior temporal gyrus.¹⁹⁵

But there is a further point that needs to be made, which though it looks similar, is subtly and importantly different. Let me put it like this. In a testing and unfamiliar situation, a military commander may decide to send in the elite troops, the SAS. The regular soldiers will be expected to maintain, and perhaps increase, their effort after the deployment of the SAS, but it is not *that* that is expected to make the difference: rather it is the addition of a new element, the skill and expertise of the special forces, *relatively* few though they may be. (For my literal-minded readers – yes, I know the brain is not an army fighting a campaign ... this is a metaphor.) As I will need to refer to it again, I will call this, for short, the SAS effect.

In this case, the left hemisphere would provide the usual language areas, the right hemisphere the special expertise required to understand metaphor.

Third, putting language aside, we know that the right hemisphere has the advantage in understanding the broad picture, as well as all that is implicit, novel, needs to be understood in context, or as a whole, and is emotionally fraught with meaning. Returning to language, what is a metaphor if it is not something implicit, whose meaning is embodied in a new image, has to be understood as a whole and in context, increases emotional impact, forges new links, and deals with a broad complexity of meaning, not a simple, narrow one? It would, then, be odd indeed if the right hemisphere were *not* better at understanding metaphor.

So how strong is the evidence that it is?

Lesion studies clearly demonstrate that individuals with right hemisphere damage exhibit inappropriate literal thinking, for which reason they often find it hard to maintain ordinary conversation.¹⁹⁶ When presented with a metaphorical phrase, patients with right hemisphere brain lesions, but not left hemisphere lesions, are generally literal-minded, and tend to select a picture representing the literal rather than the figurative meaning ('I have a heavy heart' indicates a report of one's cardiac hypertrophy).¹⁹⁷

Fig. 19. 'It was a dark day for Denis' Anita Klein, 1991 (from a series of 16 commissioned by the author)

Visual field studies¹⁹⁸ and event-related potential studies confirm a right hemisphere advantage for metaphor comprehension.¹⁹⁹ TMS stimulation of the right, but not the left, dorsolateral prefrontal cortex, caused improvement in understanding of metaphors in patients with Parkinson's disease.²⁰⁰ TMS demonstrates the critical involvement of right, but not left, posterior temporal cortex, in the understanding of novel metaphors.²⁰¹ And an overview of more than 60 behavioural and scanning studies to date found a coherent pattern: the right hemisphere is better wherever there is non-obvious, non-literal meaning – including therefore, of course, metaphors.²⁰²

Most, but not all (usually for the reasons I have just outlined) functional scanning studies confirm this right hemisphere involvement in metaphor comprehension.²⁰³ In particular, they confirm the role of the right temporal lobe,²⁰⁴ the right temporoparietal junction,²⁰⁵ the right parietal region²⁰⁶ and the right insula,²⁰⁷ as well as the right medial frontal and prefrontal cortex.²⁰⁸ I draw attention to this level of detail here because it

demonstrates that metaphor comprehension is widely distributed *throughout* the right hemisphere. Hence the futility of trying to break down metaphor into ever smaller parts, and seeing metaphor as a specialised, highly local, linguistic function, since it is a *whole way of understanding reality, intrinsic to the way of being in the world mediated by the right hemisphere*.

It is obvious that metaphor induces more emotion than literal language, hence its use in poetry: unsurprisingly therefore it excites more deep-lying areas of the limbic system involved in emotional activity, including the amygdala and anterior hippocampus.²⁰⁹ The left hemisphere does not so readily understand emotional meaning. And the right temporal region is essential for the integration of two seemingly unrelated concepts into a meaningful metaphoric expression.²¹⁰ Unfamiliarity requires longer working memory, a feature of the right hemisphere,²¹¹ so that the phenomenon may be held in suspension without collapsing it into something familiar: right (but not left) middle and inferior frontal regions have been specifically related to such activity.²¹²

Studies of every kind examining indirect meaning in language – certainly metaphor, but also humour, irony and sarcasm, as we have recently seen – consistently report key activity in regions of the right hemisphere. For these, perspective-taking²¹³ and affective processing²¹⁴ are required; and both are also, independently, known to be superior in the right hemisphere.

In conclusion, then, there is here not just a narrow linguistic function, not just some kind of specialist language ‘module’ somewhere tucked away in the right hemisphere, but the *modus operandi* of the right hemisphere as a whole. The right hemisphere, in effect, becomes crucially involved whenever the question involves *meaning that is not revealed by simply following the rules*.

Here, as elsewhere, the hemispheres have a relationship of reciprocal inhibition, which it is part of the function of the corpus callosum to maintain.

Interpreting fine social signals

Our gut feelings about one another lead to conclusions that are hard to articulate, involve parallel processing of complex material and require fine

perception – all of which suggests that the right hemisphere will play a key role. Such feelings arise in social situations, where an important element is the making of very quick decisions about another human being – their intentions, how far they can be trusted, and so on. We know that this depends largely on the fronto-insular cortex of the right hemisphere.²¹⁵ (This is the same part of the brain that also reacts, instantaneously, in mothers, to the cries of distressed infants.)²¹⁶ It makes sense that these same areas of right fronto-insular cortex do not function normally in subjects with autism;²¹⁷ and there is a strong correlation between reduced activity in the right anterior insula and poorer performance on social tasks in autistic subjects, as revealed by a meta-analysis of 24 functional imaging studies.²¹⁸ Intriguingly, these same areas of the right hemisphere are both structurally and functionally unduly *prominent and active* in a relatively uncommon condition called Williams syndrome, in some senses the antithesis of autism, a chromosomal abnormality which results in ‘hyper-social’, highly empathic, anxious to please, behaviour.²¹⁹

The right anterior cingulate cortex, which has a hugely important role in relating emotion to cognition in normal subjects, is about 13% larger than its counterpart on the left – a highly significant differential.²²⁰ And what is more, it contains special fast-conducting nerve cells called von Economo neurones (after their description by Constantin von Economo, an Austrian psychiatrist and neurologist of Greek origin). These are specialised, spindle-shaped neurones, which seem to be found only in highly intelligent mammals, including the great apes, elephants, dolphins, whales, and a few other species, such as macaque monkeys, and may represent an instance of convergent evolution.²²¹ They are to be found only in three areas of the brain that are interconnected, and that are deeply bound up with empathy, social judgments and ‘gut feelings’: the anterior cingulate cortex, the fronto-insular cortex, and the dorsolateral prefrontal cortex. They are much more numerous in the right hemisphere in mature human individuals.²²² Furthermore, there is evidence from a developmental MRI study based on 316 right-handed subjects that the anterior insular and posterior orbitofrontal cortex, while thinner on the right than the left at age four, progresses by age 20 to be significantly thicker on the right.²²³ A fascinating finding is that von Economo neurones in the anterior cingulate cortex of the right hemisphere are reduced in early-onset schizophrenia –

as, of course, is empathy, social understanding and intuitive understanding.²²⁴

It seems likely, then, that when our gut feelings concern another human being, these are going to be underwritten largely by the right hemisphere. A key observation in dealing with intuition *in general* may be that the maintenance in working memory of non-verbal information, so crucial to gut feelings, depends on the right dorsolateral prefrontal cortex.²²⁵

In the world we live in, the word ‘emotional’ is almost intrinsically imbued with the idea of excess. To be emotional is to be out of control. It may help to realise that, since the right frontal cortex is essential to emotional understanding, it is also the seat of *inhibitory* control over emotional arousal.²²⁶ Anger is the hardest emotion to regulate, perhaps because it is left-lateralised, while emotional regulation is right-dominant. Self-control in different psychological domains depends on the right pars opercularis (the posterior part of the inferior frontal gyrus).²²⁷ Psychologists have measured how frequently individuals use the word ‘not’ in verbal or written language: this propensity, called activity inhibition, appears ‘to engage functions of the right hemisphere and disengage functions of the left hemisphere... A meta-analysis ... corroborated that activity inhibition is reliably associated with right-lateralised attentional sensitivity in general’.²²⁸ When activity inhibition is high it moderates the expression of the need for power, such that it is more sensitive to context and more orientated towards others; when it is low, behaviour is more power-seeking, self-centred and narcissistic.²²⁹ Being emotionally savvy doesn’t mean that one is at the beck and call of emotions – rather, the reverse. The irritable, angry and at times inappropriately elated attitude of the left hemisphere tells one that deep emotional engagement is not its forte.

The take-home message here is not so much to do with emotion in the popular sense. Too often this suggests the antithesis of ‘cool’ intelligence. However, emotion is a critical part of our capacity to comprehend the world at all, the ability to *understand* and *interact* with other living beings. Without it we are foolish, however much we may know, and we are only alive in a diminished sense of the word. Antonio Damasio describes a man

– ‘Elliot’ – who was unfortunate enough to have lost intuitive and emotional understanding, and whose life ground to a standstill, because every decision had to be calculated from first principles – as if by a machine, from ‘outside’.²³⁰ As with everything else to do with the right hemisphere that we have looked at so far, it is a matter not of *manipulating* the world, but of *understanding* it. And belonging to it. Indeed it is not so much a matter of *cogito ergo sum*, as *sentio ergo sum*.

SUMMARY

Social and emotional understanding are central to understanding all human situations. The evidence is that the right hemisphere is of critical importance for this, including the sense of reality itself, the ability to understand what another person knows, how that differs from what you know, what they mean and what their unspoken intentions might be. The right hemisphere is superior at emotional expression and receptivity. It is crucial for empathy and for a sense of agency. It is important for understanding implicit meaning, in all its forms, including metaphor, and for reading faces and body language. It understands how context changes meaning. In all these respects, the evidence is that it is superior to the left hemisphere.

COGNITIVE INTELLIGENCE

It appears that the right hemisphere may not be so dumb after all.

—Stephen Fiore & Jonathan Schooler¹

MOST PEOPLE, FAMILIAR WITH THE POPULAR MISCONCEPTION OF HEMISPHERE difference, would think that intelligence is based largely on what the left hemisphere contributed, while the right hemisphere perhaps contributed to emotional intelligence, if anything. The truth might surprise them. Bear in mind that intelligence is about *understanding*, which is not the left hemisphere's forte: its strong suit is following familiar procedures. Intelligence is revealed in seeing how to use what one knows already to tackle a problem never, in that precise form, seen before – it is creative (the subject of the next chapter).

Although higher intelligence has increased the need for brain specialisation – requiring a ‘virtual’ version of the world for us to manipulate in the left hemisphere – that does not mean that the left hemisphere is in itself the more intelligent.² Increased intelligence has enabled us to develop computers, and computers in turn can aid our intelligence; but they are intermediaries in that process, not themselves the source of our intelligence. While the left hemisphere is not a computer, it is an intermediary, an emissary – better at carrying out procedures than understanding their meaning.

Measuring intelligence is controversial, partly because, like everything else that matters, it is hard to pin down. This has – in a reflex that should by

now be familiar – led to people claiming it doesn't exist. Such people remind me of a story told by the biologist Sir Peter Medawar. 'I once spoke to a human geneticist', he wrote, 'who declared that the notion of intelligence was quite meaningless, so I tried calling him unintelligent. He was annoyed, and it did not appease him when I went on to ask how he came to attach such a clear meaning to the notion of lack of intelligence. We never spoke again.'³

More seriously, it's no good just throwing up our hands in despair and saying we don't know what intelligence is. In life we know it when we see it. Linda Gottfredson and 52 leading experts published the following definition in the *Wall Street Journal* in 1994 (it was based on an academic paper subsequently published in the journal *Intelligence*):

Intelligence is a very general mental capacity which, among other things, involves the ability to reason, plan, solve problems, think abstractly, comprehend complex ideas, learn quickly and learn from experience. It is not merely book learning, a narrow academic skill, or test taking smarts. Rather, it reflects a broader and deeper capability for comprehending our surroundings – 'catching on', 'making sense' of things, or 'figuring out' what to do.⁴

This seems to me a fair description; and by common consent the measure that most reliably corresponds to it is what is known as *g* (for 'general' intelligence).

IQ scores are one way, probably the commonest, of assessing *g*. It might be thought that, because there are a number of subtests in an IQ assessment, *g* was itself an aggregate, but it seems that it behaves as a single factor underlying all intelligence assessments: subjects who are good at one test will usually be good at the others. According to Stuart Ritchie, lecturer in psychology at King's College London and author of *Intelligence: All That Matters*, this is one of the most robustly replicated findings in all of psychological research.⁵ *g* scored in childhood correlates closely with *g* through to old age, and is predictive of many factors, including earning power and longevity.

The *g* factor involves different types of intelligence. It is conventional to distinguish *Gf*, which signifies 'fluid' intelligence, from *Gc*, signifying

‘crystallised’ intelligence. The intended distinction here is between, as far as possible, intelligence in and of itself, that can therefore be applied to any new situation or set of factors, and is hence ‘fluid’; contrasted with that which requires a certain context, builds on education, general knowledge, experience and cultural factors, and is in that sense ‘crystallised’. Clearly, people with high scores on fluid intelligence will tend to do better, and to work faster, in their culturally defined contexts as well, so G_c will to some extent reflect G_f . But it is G_f that is least culture-bound, and the best correlative of intrinsic intelligence.

A study from the Decision Neuroscience Laboratory at the University of Illinois is striking. In agreement with a broad consensus, they write that ‘in factor analytic studies, the best tests of g involve fluid intelligence or novel problem solving’.⁶ High performance in such tests is predictive of broad success in many different kinds of cognitive activity, from educational and work achievements to social well-being.⁷ The study looked at the impact of brain lesions on intelligence in 158 patients, a substantial sample. Its conclusion was surprisingly clear (see Plate 12[a]). G_f , they found, was

associated with a broadly distributed network of brain regions *primarily within the right hemisphere* ... This pattern of findings suggests that G_f reflects the ability to effectively integrate verbal, spatial, motor, and executive processes via a *circumscribed set of cortical connections in the right hemisphere*.⁸

Long white matter tracts in the right hemisphere were found to be particularly significant, eg, the superior longitudinal (and arcuate) fasciculus; which confirms previous research demonstrating their importance for general intelligence.⁹ To the extent that G_f relies on pattern recognition and ‘novel problem solving’, its right hemisphere dependence would be expected.

The researchers also show brain maps of working memory for (1) monitoring information, (2) manipulating information, (3) verbal and numeric representation, and (4) spatial representation. Monitoring information and spatial representation are almost entirely in the right hemisphere; manipulating information and representation in words and numbers almost entirely in the left.

This is one of a number of studies that point in the direction of intelligence depending preponderantly on the right hemisphere. Several reviews of the evidence have concluded that intellectually gifted subjects demonstrated more prominent right hemisphere activation than controls, especially in mathematical reasoning ability (the ability to discern patterns, though not necessarily computational skill).¹⁰ However, it is seen across the board:

There is strong evidence [in the intellectually gifted] for an uncharacteristically high level of involvement of the right hemisphere in all types of cognitive task performance (*including linguistic ones*), as well as indications of enhanced co-ordination and allocation of cortical resources between the hemispheres during intellectual engagement.¹¹

In most circumstances it seems likely that both hemispheres working together are going to be superior to either alone. What happens when one hemisphere has to be surgically removed, as is sometimes medically necessary? Data from surgical removal of a hemisphere are inconclusive. An early review suggested that, while full-scale IQ is lowered whichever hemisphere is ablated, the impact is consistently less when the left hemisphere is the one that is removed.¹² One person actually developed above normal language and intelligence after left hemispherectomy.¹³ In a more recent study, five paediatric patients had left hemispherectomy, of whom only one showed a significant drop in IQ; two had right hemispherectomy, both of whom showed a significant drop in IQ.¹⁴ However, the numbers are clearly small, which limits their general application; and a much bigger follow-up study found no significant difference in IQ by side of hemispherectomy.¹⁵ This finding may reflect the fact that in childhood the brain exhibits a high degree of plasticity.

While IQ tests are broadly a measure of g , some subtests are more correlated with g than others, and they may be to some degree subject to practice effects: a topic I will come back to. However, there are one or two physiological measures that have been found consistently to parallel g closely, and to be free from any possible training effect.¹⁶ The best known and best attested is simple reaction time: literally how ‘quick’ you are to

react appropriately to a stimulus, such as cancelling a light. It is closely related to information processing speed, and is said to be a culturally neutral biological marker of *g*.¹⁷ Shorter reaction times (whether in simple or four-choice tests) are strongly associated with general intelligence, and the correlation increases with age.¹⁸ Another physiological measure is colour discrimination ability: ‘colour acuity is strongly correlated with *g*’.¹⁹ Such a correlation turns out to be surprisingly strong, between approximately 0.7 and 0.9.²⁰

Colour acuity (as we have already seen) is associated with the right hemisphere.²¹ Is speed of reaction time? Two early studies of brain-damaged patients found that right hemisphere-damaged patients showed much greater impairment on simple reaction times than left hemisphere-damaged patients.²² So surprised were the experimenters, especially given the prevalence of right-handers (which would perhaps favour left hemisphere reaction times), that they assumed this must be because the right hemisphere-damaged group had larger lesions; but on metric analysis it turned out that they in fact had smaller lesions.²³ In other words, those with lesions in the right hemisphere, despite the lesions being on average smaller, showed the greatest losses in reaction time. On the basis of these results, the authors of a subsequent study noted that ‘it is difficult to escape the inference that the hemisphere which is non-dominant for speech is in some way dominant for simple reaction time’. After carrying out their own testing of 81 subjects (29 with left hemisphere damage, 20 with right hemisphere damage and 32 controls), in 8,100 individual trials, they concluded that ‘the effect is asymmetrical, lesions of the non-dominant [right] hemisphere producing far greater impairments than those of the dominant [left] hemisphere’.²⁴

These findings would, of course, be in keeping with the evidence that intelligence is largely right hemisphere-dependent. In case we seem to have strayed too far from the realm of mathematical intelligence, which is probably for most people, if they are honest, a ‘gold standard’ of what they mean by intelligence, it seems clear that the right hemisphere is strongly linked to maths intelligence. Those who are maths-intelligent show enhanced development and activation of the right hemisphere.²⁵ Maths-intelligent children showed the most significant differences in three areas,

all in the right hemisphere – the inferior parietal lobule, postcentral gyrus, and premotor cortex.²⁶ (See also Appendix 1.)

This is in keeping with the fact that human intelligence is not like machine intelligence – modelled, as that is, on the serial procedures so typical of the left hemisphere. Comparing artificial intelligence with human intelligence, and indeed that of organisms more generally, the microbiologist Brian Ford writes that ‘to equate such data-rich digital operations with the infinite subtlety of life is absurd’, since intelligence in life operates

on informational input that is essentially *Gestalt* and not digital. [Living systems] can construct conceptual structures out of non-digital interactions rather than the obligatory digitized processes to which binary information computing is confined.²⁷

What has been happening to *g*, our intelligent capacity to make sense of the world? I will argue in this chapter that it is in decline because we are increasingly wearing what James Flynn, one of the most famous living intelligence researchers, calls ‘scientific spectacles’. What this amounts to is that the right hemisphere understanding is being ‘elbowed’ out by the left hemisphere’s insistence that we see the world *its way*: even though this way is less intelligent.

The Flynn effect

But surely, the informed reader may ask, is it not precisely Flynn who suggested that intelligence is increasing? Flynn’s name has, after all, been lent to this development – the ‘Flynn effect’.

In the mid-1980s, Flynn, a researcher at the university of Otago in New Zealand, noticed that there seemed to be a general trend since the 1930s for IQ in Western countries to have risen significantly, by something in the order of three points per decade.²⁸ Subsequent data reinforced Flynn’s finding.²⁹ IQ scores are standardised on the population so that 100 represents the mean. Every so often the tests have to be re-standardised on the current population, and by comparing subjects’ scores on the previous

test and the new test, it was possible to detect a rise. This phenomenon is the Flynn effect and is very widely accepted.

How do I reconcile this, and the clear finding that intelligence depends on the right hemisphere, with my contention that, as a society, we in the West rely more and more on the left hemisphere? Shouldn't IQ be *declining*, not increasing?

There's more than one puzzle here. As Flynn himself pointed out more recently, if huge IQ gains were really intelligence gains, why are we not struck by the extraordinary subtlety of our children's conversation? Why do we not have to make allowances for the limitations of our parents? A difference of some 18 points in the average IQ over two generations ought to be highly visible. As he put it,

In 1900, the average IQ scored against current norms was somewhere between 50 and 70. If IQ gains are in any sense real, we are driven to the absurd conclusion that the majority of our ancestors were mentally retarded ... Either today's children are so bright that they should run circles around us, or their grandparents were so dull that it is surprising that they could keep a modern society ticking over. ³⁰

Or both. Clearly something odd was happening. Because at the same time, evidence from other sources suggested that the precise *opposite* was the case: intelligence was in decline.

Despite relentless propaganda from government in a yearly ritual claiming improvement in exam results for, say, science and maths, university lecturers noticed a decided decline in ability. For example a study published by the Engineering Council of London in 2000, prompted by university-level concern, presented evidence of 'a serious decline in students' mastery of basic mathematical skills and level of preparation for mathematics-based degree courses. This decline is well established and affects students at all levels.'³¹ Teachers from 60 university departments had used their own means of testing their incoming students' mathematical competence, and found a decline in basic mathematical skills in relation to the same A-level grades, with the decline starting in 1985. There is clear evidence that just such a lowering of standards, combined with inflation of

grades, has occurred.³² Comparing with the International Test of Developed Abilities as a benchmark, it has been demonstrated that, just between 1996 and 1999, grade inflation in A-level maths was nearly one whole grade – in only three years.³³

Maths and engineering is one of those areas in which such declines can be more easily measured than in the humanities, though similar observations have been made there. For example, a recent report on American College Testing (ACT), a standardised test used for college admissions in the United States, found that ‘without real reforms in K–12 [school, in British English] education, we will continue to see too many high school graduates entering college ill-prepared for credit-bearing college coursework and too few students earning a college degree’³⁴ – this in a nation in which those who say they have not read a single book in the last year rose from 16% in 2013 to 27% in 2019.³⁵

Another way of testing the acquisition of true understanding, rather than just ‘test smarts’, is to apply Piagetian educational stage assessments. Doing so confirms the decline. There is a test called ‘Volume and Heaviness’, which requires an understanding of how much water an object will displace. Researchers chose to look at it because it has been shown to have ‘substantial predictive validity for both science and mathematics achievement’.³⁶ To succeed at this test, 11–12 year-old children

need to have established that it is the volume of the blocks, not their weight, that determines how much water they will push aside. In 1976 many more girls than boys had an implicit model that the weight is the determining cause. The average success rate on this item in 1975/76 was 54% for boys and 27% for girls, and by 2003/04 the differential had completely disappeared, with the success rate for both at 17%.³⁷

Success of a kind, depending on what you want your results to show. As the authors comment, ‘the much higher drop by boys in this period seems to tie up with other evidence on the deterioration of boys’ learning, relative to girls, in schools. It makes it difficult to believe in the validity of the year on year improvements reported nationally ...’³⁸

On two other Piagetian tests, the Equilibrium and Pendulum tests, the results are similarly troubling. ‘From about 1975–1976 to 2006–2007, both show a huge decimation of the top scorers who could achieve at the early formal level: down from 20.35% to 4.80% and from 23.80% to 11.65% respectively ...’³⁹ I will return to the significance of Piagetian tests shortly.

The Flynn effect is not the only thing that requires explaining. There is also the subsequent reverse Flynn effect.

The reverse Flynn effect

More recently many studies have reported a ‘reverse Flynn effect’. This is a reversal of the direction of the curve: namely a year on year *decline* in intelligence test results, comparable to the original positive Flynn effect. In Finland, where military service is compulsory and where all recruits are tested using the Finnish army’s own intelligence tests, after year on year rises in three subtests during the decade to 1997, ‘from 1997 to 2009 there were declines in all three tests averaging 2.0 IQ points a decade’.⁴⁰ Such studies of entire conscript populations are available for a number of countries, and ‘allow us to conclude that there is a continuous decline in IQ scores over time and that this is a real phenomenon and not simply a blip’.⁴¹ Apart from Finland, average IQs *declined* from the mid-1990s in Norway,⁴² Denmark,⁴³ Estonia,⁴⁴ Britain,⁴⁵ France,⁴⁶ the Netherlands,⁴⁷ and Australia.⁴⁸

Flynn himself has been quick to acknowledge this phenomenon and to engage with it. In the United Kingdom, a study by Flynn found that tests carried out in 1980 and again in 2008 show that the IQ score of an average 14 year-old dropped by more than two points over the period.⁴⁹ Not good news, but there is a more worrying rider to this. Declines at the top end are steeper: ‘for the upper half of the results the performance was even worse’. Here IQ scores declined by six points. Flynn argues that the drop may be due to youth culture emphasising computer games at the expense of wider cultural stimulation, real-world play, reading books and conversation.

‘The Piagetian results are particularly ominous’, he writes:

Looming over all is their message that the pool of those who reach the top level of cognitive performance is being decimated: fewer

and fewer people attain the formal level at which they can think in terms of abstractions and develop their capacity for deductive logic and systematic planning. They also reveal that something is actually targeting that [ie, the top] level with special effect, rather than simply reducing its numbers in accord with losses over the curve as a whole ... [50](#)

And in a recent article Flynn and colleague Michael Shayer write that

...the decimation of top scores may be accompanied by gains in cognitive ability below the median. [Piagetian tests] also reveal the existence of factors that have an atypical impact at high levels of cognitive competence. Scandinavian data from conventional tests confirm the decimation of top scorers but not factors of atypical impact. Piagetian tests may be more sensitive to detecting this phenomenon. [51](#)

What emerges is that there are conflicting trends between those at the highest level of cognitive development and those ‘in the early stages’ of the next level down. Large losses at the highest level may be accompanied by gains at a lower one. [52](#) Repeating that there has been ‘without doubt a decimation of those with high cognitive ability’, they conclude:

In sum: at one time the best of Britons (aged 12–14) could cope with items on the formal level and blended into a smooth curve of performance. Now these items are beyond many of them and register as a huge decimation of high scorers ...’ [53](#)

So what happened?

It seems that a number of elements are involved.

First, initial improvements were made by picking ‘low hanging fruit’. Those at the bottom of the range could perhaps be expected to improve with better levels of nutrition, with more hours spent in full-time education, and above all with more targeted test-training. The ‘nutrition hypothesis’ predicts that gains will occur predominantly at the low end of the IQ

distribution, where nutritional deprivation is probably most severe.⁵⁴ Because there are many more in the bottom half of the distribution than there are at the very top, there appears to have been a general increase, while those at the very top, on whom universities, research innovation and ultimately national prosperity disproportionately depend, have suffered a serious decline.

Second, it seems that the sub-score increases, where they existed, were greatest in those areas that do not load heavily on *g*, the most reliable correlate of general intelligence, which a substantial body of research suggests is largely inherited.⁵⁵ According to a Dutch research team,

low-*g* participants increased their scores more than high-*g* participants ... The generalizability of test scores resides predominantly in the *g* component ... it is easy to understand why the score gains did not generalize to scores on other cognitive tests and to *g*-loaded external criteria.⁵⁶

A number of researchers have shown that the *positive* Flynn effect, the initial gain, was unrelated to *g*.⁵⁷ In fact the evidence is that the Flynn effect gains were *negatively* correlated with *g*.⁵⁸ The implication is that an improvement in results on IQ testing had nothing to do with increasing intelligence, but with ability to carry out IQ tests satisfactorily as a result of practice.

On the other hand, the *negative* Flynn effect, the more recent decline, *does* appear to load heavily on *g*.⁵⁹ Michael Woodley has suggested that there are two quite distinct effects operating, in opposite directions, a phenomenon he terms ‘co-occurrence’. The Flynn effect (rising IQ) is compatible with persistent decreases in real intelligence, and both can occur simultaneously. The idea here is similar to that proposed to explain cooling effects on the background of global warming: despite a relentless upward drift in global temperatures in the longer run, temporarily supervening cycles can independently produce, for a while, a run of colder winters. Thus while ‘genotypic intelligence’ (the level of intelligence said to result from the action of genes alone) has been declining, these declines have been offset by gains in ‘phenotypic intelligence’ (the intelligence said to result from the interaction between a population’s genes and improved

environments), as if, in an image used by one behavioural geneticist, a rising tide floated nonetheless leaky boats.⁶⁰

Third, there has been, since the 1930s, and particularly since the 1980s, a considerable focus on test-taking skills, in the hope that it might improve maths skills overall (though apparently without any positive effect in that regard). Practice might well, though, have merely caused an increase in skill at IQ test-taking.⁶¹ Indeed, there is good evidence that the Flynn effect is partly due to this change in school practice. Re-taking an IQ test usually leads to an increase of about three points in score, obviously without intelligence having changed. So while it seems likely that there have been increases in non-*g* related intelligence in the lower part of the intelligence range, the Flynn effect is due in part to increases in test-specific skills, practice effects and ‘teaching to the test’, a conclusion reached by a wide range of researchers in different countries.⁶² Arthur Jensen, the leading exponent of the importance of *g* in measuring conceptual intelligence, also pointed out that IQ, though not *g*, could be artificially inflated by training and retesting, without any significant real-world effects in terms of intelligence.⁶³

One irony, commented on by Flynn in a paper in 1987, is that, since a test known as Raven’s matrices, based on shapes not words, has been thought to be the least subject to culturally loaded words or symbols, it has been promoted as a culture-free measure of intelligence. For that very reason it has been so widely subject to coaching that it has become, in Flynn’s words, the ‘purest measure of those problem-solving skills that are most subject to cultural determination’, and as a result ‘culturally reduced content has maximized culturally influenced performance’.⁶⁴ Although Raven’s matrices invite one to ‘see’ the appropriate shape to complete the task, using inventive and analogic (right hemisphere) thinking, there are teachable algorithms that enable solving in a purely systematic (left hemisphere) fashion, without insight.⁶⁵ These were not formerly taught in school, but now often are. Their results then come to measure not so much intelligence, as diligence.

Some might say, ‘Well, if so, why worry? The same ends are reached.’ But they are not. First of all, intelligence is not being measured: following familiar procedures is something that requires no intelligence and can be done by a machine. It is the ‘novel problem solving’, involving a combination of analogic thinking and going beyond learnt procedures, that

should be being measured. In the second place, and obviously, diligence is even more productive when applied to higher intelligence, so if we are really experiencing losses of intelligence at the top end, they are so great that even diligence cannot make up for them. And in the third, there are many situations – including all truly new and therefore potentially creative ones – where diligence can be no kind of match for intelligence.

As mentioned earlier, there are one or two physiological measures that have been found consistently to parallel IQ closely, and to be free from any possible training effect: reaction time and colour acuity.⁶⁶ Simple reaction time has been measured in large populations since the middle of the nineteenth century, and has been found to be declining since the late nineteenth century.⁶⁷ Using it as a measure suggests a real decline of 13.3 IQ points between 1884 and 2004.⁶⁸ Colour acuity shows a similar trend.⁶⁹

I have mentioned a number of possible factors – including teaching to the test – leading to the ‘positive’, and subsequently ‘negative’, Flynn effect: an apparent increase in IQ, and its subsequent reversal. But there is another intriguing possible explanation that Flynn himself has put forward. This may be, as Aleksandr Luria, the ‘father of neuropsychology’, before him believed, that we have started to see the world through what Flynn calls ‘scientific spectacles’:

The scientific world-view, with its vocabulary, taxonomies, and detachment of logic and the hypothetical from concrete referents, has begun to permeate the minds of post-industrial people ... Today we have no difficulty freeing logic from concrete referents and reasoning about purely hypothetical situations. People were not always thus.

From interviews Luria conducted with peasants in remote areas of Russia, [Christopher] Hallpike culls some wonderful examples.⁷⁰ The dialogues paraphrased run as follows:

Q: All bears are white where there is always snow; in Novaya Zemlya there is always snow; what color are the bears there?

A: I have seen only black bears and I do not talk of what I have not seen.

Q: But what do my words imply?

A: If a person has not been there he cannot say anything on the basis of words. If a man was 60 or 80 and had seen a white bear there and told me about it, he could be believed ...

The peasants, of course, are entirely correct. They understand the difference between analytic and synthetic propositions: pure logic cannot tell us anything about facts; only experience can. But this will do them no good on 'Similarities' [an IQ subtest type].⁷¹

From the beginning of IQ testing, purely formal categorisation has been permitted to score more highly than concrete categorisation. According to Flynn, stating that a pound and a yard are 'both measures' (their general category) earns a higher score than saying 'you can measure things with them' (a main function of each); and calling something a 'feeling' is less concrete (and worth a higher score) than 'the way you feel'. The abstract noun (a thing), is privileged over the verbal phrase (a process). However,

a person who views the world through pre-scientific spectacles thinks in terms of the categories that order perceived objects and functional relationships. When presented with a Similarities-type item such as 'what do dogs and rabbits have in common', Americans in 1900 would be likely to say, 'You use dogs to hunt rabbits'. The correct answer, that they are both mammals, assumes that the important thing about the world is to classify it in terms of the taxonic [*sic*] categories of science. Even if the subject were aware of those categories, the correct answer would seem absurdly trivial. Who cares that they are both mammals? That is the least important thing about them from his point of view.

As you will recognise, this is to privilege the left hemisphere's way of looking at the world over that of the right hemisphere. And, as if in confirmation, a patient with his right hemisphere removed performed well on the Similarities test (IQ-equivalent 128): 'most of his definitions on the Vocabulary test were abstract. Objects were defined in terms of their membership in a wider class rather than in descriptive terms.'⁷²

'The preference for taxonic answers (categories that classify the world and extra credit for the vocabulary of science)', Flynn continues, 'is

extraordinary’; and it reached an even higher level by 2003, where previous advice to those administering the Wechsler Intelligence Scale for Children to give one out of two for concrete answers is replaced by ‘merits no or only a partial credit’.⁷³ The implication is that

if children use pre-scientific spectacles, they can get no more than half credit on most Similarities items. If the children of 1900 were given a prehistoric version of the WISC-IV, they would have a raw score ceiling of 22. This is at the 25th percentile of contemporary children aged 14 ... The hypothesis is that our ancestors found pre-scientific spectacles more comfortable than post-scientific spectacles, that is, pre-scientific spectacles showed them what they considered to be most important about the world. If the everyday world is your cognitive home, it is not natural to detach abstractions and logic and the hypothetical from their concrete referents. It is not that pre-scientific people did not use abstractions: the concept of hunting as distinct from fishing is an abstraction. They would use syllogistic logic all of the time: Basset hounds are good for hunting; that is a Basset hound; that dog would be good at hunting. They would of course use the hypothetical: if I had two dogs rather than only one, I could catch more rabbits ... [But] today we are so familiar with the categories of science and are so imbued with the scientific world-view, that it seems obvious that the most important attribute things have in common is that they are both animate, or mammals, or chemical compounds ... Our ancestors in 1900 were not mentally retarded. Their intelligence was anchored in everyday reality. We differ from them in that we can use abstractions and logic and the hypothetical to attack the formal problems that arise when science liberates thought from concrete referents.⁷⁴

Given this drift toward rewarding decontextualised thinking, it makes sense that today’s children are better at it: they do not have a rich web of naturally embodied experience to unlearn. What looked like a rise, for a while, in IQ may have been the increasing adoption of Flynn’s ‘scientific spectacles’, and a tendency to award higher marks for such a view.

Flynn has another observation to make that is also relevant. On a subtest known as Vocabulary, there had been an increase between 1971 and 2007 of 0.35 IQ points per year.⁷⁵ However, on a test of spatial ability, the ‘3DC’ or Three Dimensional Cubes test, there had been a loss of 0.48 points per year from 1977 to 2014.⁷⁶ And he continues, referring to the researchers,

They do not give a decade-by-decade break down; but their graph shows a rise to 1995 and a loss thereafter, thus implying that the rate of loss was greater than 0.48 per year between 1996 and 2014. We can find no plausible explanation of why vocabulary and spatial ability trends diverge ...

I could hazard a guess. Vocabulary is a left hemisphere test, and so scores have improved; 3DC is a right hemisphere test, and so scores have declined.

I started by asking how I could reconcile the clear findings that IQ scores depend on the right hemisphere, and that IQ scores have increased until recently, with my view that, as a society, we in the West rely more and more on the left hemisphere. My answer is that a number of factors are involved. Only some aspects of IQ – those not strongly *g*-related – have increased for some sectors of society, almost entirely in response to temporary extrinsic factors, such as better nutrition, more time spent in school, and teaching to the test, factors that can be relied on to achieve rapid gains over the short term, but will tail off, as they in fact have, as the ceiling of such effects is reached; that such factors apply across a large sector of the population, those below the mean, with the biggest sacrifice being made at the small, but significant, top end of the scale, among the gifted, who, as we know from other sources, rely particularly on the right hemisphere. And the overall trend is downward, as we now see in most highly industrialised Western countries, where the ‘low hanging fruit’ have been gathered, and no further windfall can be expected: only the effects of overall decline in intelligence, at least as things stand today.

As I write, Norwegian research on within-family changes in IQ over time shows a decline in intelligence scores of about seven points per generation, starting with those born about 40 years ago. While this does not rule out additional effects due to changing population composition, it does

establish that the large changes in average intelligence must be to a considerable extent due to environmental factors in the society in which children are growing up.⁷⁷

SUMMARY

Evidence from a number of sources suggests that the right hemisphere contributes the majority, not just of emotional and social intelligence, but also of what is ordinarily meant by intelligence (IQ) – cognitive power, or *g*. This appears to be particularly true among children and adults of the highest intelligence. Possible reasons for the apparent earlier increase and subsequent decrease in intelligence in the general population over recent decades are explored.

CREATIVITY

The mind in creation is as a fading coal ...

—*Percy Bysshe Shelley*¹

One should say ‘it thinks’, just as one says: ‘it’s lightning’

—*Georg Christoph Lichtenberg*²

CREATIVITY IS NOT A PURELY HUMAN PREROGATIVE. THE ABILITY TO invent, to respond in a way that is not programmed, is essential to survival. It is part of every living creature’s repertoire in its own degree, making new responses to changing circumstance. We know that the capacity to innovate in birds and animals is directly linked to their capacity for survival.³ Barbara McClintock even described creative innovation in the face of a novel threat by single cells, an observation that has been repeatedly confirmed. However, this capacity has reached extraordinary heights in humans, because of our ability to imagine.

In this first part of the book, I have been considering the means to truth, those faculties that our brains and minds come equipped with, which open the world to us, or alternatively obscure it from us. In Part II, I will be looking at what one might call the paths to truth, the ways in which in our lives we evaluate over a longer period of time what we are willing to accept as having at least a degree of truth, and reach a deeper understanding. These

paths, I suggest, might be thought of as those of science, reason, intuition and imagination.

This distinction between means and paths is, like most distinctions applied to the being of humans, clearly not hard and fast. And perhaps the faculty that most clearly straddles the border is imagination. What I have chosen to do is to look here, in Part I, at a certain aspect of the imagination, the creative faculty, and its hemisphere correlates, since it involves a focus on neuropsychological detail. In Part II, when I move beyond the means proffered by the hemispheres to the *paths of approach* to truth, I will consider the part played by imagination more broadly in bringing about an understanding of the world. Conventionally we think of art as the vehicle by which imagination discloses truth; and so it is. But I shall go further and argue that imagination is fundamental to *all* approaches to truth – not least to science.

For now, though, I will restrict myself to how the functioning of the hemispheres bears upon the role of creativity in our comprehension of the world.

Creativity is such an elusive phenomenon that one has to be creative oneself in how to approach it, since it can't be summoned at will, and the very act of attending to it inhibits it. Not a promising place for the researcher to start. It's no good putting people into a scanner and telling them to 'be creative', but you can ask them to find solutions to conundrums of various kinds. When neuroscientists look at 'the creative brain', much of the evidence understandably therefore concerns problem-solving. Findings in laboratory tasks considered suitable proxies for real-life functions often bear no relation to the real-life function that they are supposed to be replicating. Since the neural substrates in either case may be widely different, this needs to be borne in mind in the ensuing discussion.⁴

Successful creativity probably requires, in most instances, a combination of elements, especially in science and technology, but also in literature, art and music. The desire to analyse creativity is understandable, and while the analysis is not likely to reveal the whole story, or even the core of the phenomenon, it might contribute something to our

understanding. If one is going to analyse, one way of trying to get to grips with the process might be to analyse the various personal characteristics thought to be necessary for someone to have creative potential. A second might be to analyse the creative process as a broad sequence of temporal phases. And a third might be to analyse it into the (possibly simultaneous) interactive cognitive requirements for the process to unfold at all.

On the first, the matter of personal characteristics, Colin Martindale, a psychologist who used EEG techniques to investigate creativity over many years, had this to say:

Creativity is a rare trait. This is presumably because it requires the simultaneous presence of a number of traits (eg, intelligence, perseverance, unconventionality, the ability to think in a particular manner). None of these traits is especially rare. What is quite uncommon is to find them all present in the same person.⁵

That seems to me to be a fair assessment; but since we are more interested in how the hemispheres interact, or fail to interact, in order to bring about creativity, I will not have much more to say about the matter of personality, interesting though it might be. I just want to draw attention to the fact that a creative person is a microcosm of the process of creativity itself: drawing together at once factors not commonly combined.

In discussions of creativity, not enough attention is paid to the obvious fact that there are different temporal stages to the process, the second way in which we might attempt an analysis. Where they have been noted, they have sometimes been described as *preparation*, *incubation* and *illumination*. (A further step of *verification* is sometimes added, though this is strictly speaking not itself creative, any more than Quality Control creates the products of which it subsequently controls the quality.)⁶

The first of these phases, *preparation*, is partly conscious and partly unconscious, partly willed and partly serendipitous, and may go on for years. It is generally associated with some pretty hard work, acquiring skills and knowledge, thinking consciously and mulling things over unconsciously, so as to prepare the fertile ground in which the seed can grow. The second phase, *incubation*, is unconscious, and not under voluntary control: it can only be impeded by conscious effort and

introspection, much as it does a plant no good to keep digging it up to see how its roots are growing. The third phase, *illumination*, flowers out of the unconscious quite suddenly, again unwilled, and is effortless and accompanied by feelings of pleasure, satisfaction and fulfilment. Insight is effectively this third phase of creativity considered in isolation: the so-called ‘light bulb’ moment. As we saw in Chapter 4, such moments are robustly associated with activity in the right amygdala and right superior temporal sulcus.

Then comes Quality Control.

Clearly, something that is conscious and willed, is going to have different brain correlates from something that is unconscious and refuses the will.

You can’t make the creative act happen. You have to do certain things, otherwise it *won’t* happen. But it won’t happen while you are doing *them*. They create the terms on which the thing will arise. It’s a question of how we dispose our consciousness – that is, how we attend. Attention is a creative act, and creation is really about the induction of a highly attentive state. It is like an ear that is listening and receptive, without actually having anything at all clear yet to hear. You’ve got to have some intimation of what it is that’s coming, however, because otherwise it couldn’t come. On the other hand, you can’t actually close down too precisely on what sort of thing it is, because if you do, you will undoubtedly close down on something *else*. It involves remaining open, and yet being able to receive something which is, in the end, quite specific and particular. (In this, it is somewhat like prayer.)

At the opening of Book XII of his greatest work, *The Prelude*, subtitled *Growth of a Poet’s Mind*, Wordsworth describes how inspiration requires both the effort by which the mind ‘aspires, grasps, struggles, wishes, craves’ and the stillness of the mind which ‘fits [the poet] to receive it, when unsought’. An effort must be made at first, but, despite the effort, inspiration still only comes unsought.

This shape – to put it in banal terms, trying, failing, relaxing and then succeeding – is a fairly good way of understanding the creative process. But the fact that it depends on unconscious processes, flexibility, openness to the unknown and undetermined, relinquishing control, making imaginative leaps, seeing analogies, metaphors and images – all elements that are more characteristic of the right hemisphere than the left – does not endear it to a

certain type of science practitioner who likes his or her world left hemisphere fashion: neat, predictable, and determined by explicit procedures that are known and can be followed whenever one wishes. Mechanical and under control, in other words; rather than messily alive and unpredictable. In this chapter we will look at some examples of how this cast of mind gets in the way of an understanding of the phenomenon of creativity.

The third way of analysing creativity that I suggested is in terms of what I called the interactive cognitive requirements of the process, since they are not necessarily temporally successive stages, but often overlap and need to be combined at different levels of consciousness at once. They might be thought of like this.

In the first place, there are *generative* requirements for creative thought. These are the necessary elements that give rise to potentially creative thinking: what must happen. Then, since it is easy to inhibit potential, there are *permissive* requirements, without which the potential will not be realised: what must not happen. And ultimately there are *translational* requirements, those without which the creative impulse will not be carried forward.

It is fairly obvious that there is less we can do actively about generative requirements than about permissive and translational requirements, but nonetheless it is the generative requirements that correspond to what most people mean by true creativity. And with good reason. Without it, the other requirements – not actively to block its arrival, and to perpetuate it somehow once it arrives – amount to nothing.

GENERATIVE REQUIREMENTS

The key element in generation seems to be the ability to think of many diverse ideas quickly, demanding breadth, flexibility and analogical thinking – seeing likeness within apparent dissimilarity. This could be, and often is, summed up as ‘divergent thinking’, a term that is deliberately (and appropriately enough) loose, but suggests the bringing together of non-adjacent ideas, adaptability of thinking and originality of approach. According to a recent meta-analysis, the largest to date, of the correlates of creativity in the brain, ‘the hallmark of creativity is divergent thinking’.⁷

JP Guilford, who coined the term divergent thinking in the 1960s, contrasted it with convergent thinking, which he saw as the ability to find the single ‘correct’ answer to standard, clearly defined questions that do not require flexibility or originality, for instance in most tasks in school and on standardised multiple-choice tests for intelligence.⁸ According to the educational psychologist Arthur Cropley, *convergent thinking* ‘focuses on recognizing the familiar, reapplying set techniques, and accumulating information’:

it is thus most effective in situations where a ready-made answer exists and needs simply to be recalled from stored information, or worked out from what is already known by applying conventional and logical search, recognition and decision-making strategies. One of the most important aspects of convergent thinking is that it leads to a single best answer, and thus leaves no room for ambiguity: answers are either right or wrong ... it involves manipulation of existing knowledge by means of standard procedures, and ... its main result is production of increased knowledge.⁹

This process leads you to what is familiar and already (at least in principle) known – not, except in very rare cases, and then as a side-effect, to something unusual or original. What I mean by ‘at least in principle’ known is this. If you ask me what the product of 1,738,652 and 67,420,971 is, I don’t know, and it might be that no-one in the history of the world ever carried out precisely this calculation; but there is only one right answer, and

I can find that answer shortly, because I know what numbers are and the rules for multiplying them. In principle, then, I know the answer, and all I have to do is follow ordained procedures to solve the problem; whereas if you ask me how many colours it takes to shade any conceivable map so that no two adjacent regions have the same colour, I'd have to think in a different way.¹⁰ New discoveries – such as creativity in maths – are rarely, if ever, a matter of problem-solving of the first kind. Nor are they in science, poetry, or anything else. Guilford was a critic of a school system that emphasised convergent, at the expense of divergent, thinking.

What divergent thinking covers is *not* just being able to make up new ideas at random – most of which would be worthless – but perceiving connexions and shapes or forms that guide thinking by analogy: to broaden a field that has become too narrow, or to find alternative ways of visualising something that has become too familiar. All the literature on creativity in whatever field makes the same point: that it is about seeing hitherto unperceived parallels, seeing shapes or *Gestalten* that others have failed to see, standing back and taking the broad view, not squinting at the same microscopic field and looking up the rule book. Talent hits a target no-one else can hit, wrote Schopenhauer; genius hits a target no-one else can see.¹¹

In a posthumously published interview on creativity, Isaac Asimov wrote about Darwin's insight:

Undoubtedly in the first half of the nineteenth century, a great many naturalists had studied the manner in which species were differentiated among themselves. A great many people had read Malthus. Perhaps some both studied species and read Malthus. But what you needed was someone who studied species, read Malthus, and had the ability to make a cross-connection. That is the crucial point, that is the rare characteristic that must be found. Once the cross-connection is made, it becomes obvious. Thomas H Huxley is supposed to have exclaimed after reading *On the Origin of Species*, 'How stupid of me not to have thought of this'. But why didn't he think of it? The history of human thought would make it seem that there is difficulty in thinking of an idea even when all the facts are on the table. Making the cross-connection requires a certain daring. It must, for any cross-connection that does not require daring is performed at once by many and develops not as a 'new idea', but as

a mere ‘corollary of an old idea’. It is only afterward that a new idea seems reasonable. To begin with, it usually seems unreasonable.¹²

Creativity involves the making of hitherto concealed connexions. As Henri Poincaré noted, creative ideas

are those which reveal to us unsuspected kinship between other facts, long known, but wrongly believed to be strangers to one another. Among chosen combinations the most fertile will often be those formed of elements drawn from domains which are far apart.¹³

Divergent, in other words. Or as Steve Jobs, the creative genius behind Apple, put it,

Creativity is just connecting things. When you ask creative people how they did something, they feel a little guilty because they didn’t really do it, they just saw something. It seemed obvious to them after a while. That’s because they were able to connect experiences they’ve had and synthesize new things ... A lot of people in our industry haven’t had very diverse experiences. So they don’t have enough dots to connect, and they end up with very linear solutions without a broad perspective on the problem. The broader one’s understanding of the human experience, the better design we will have.¹⁴

Linear approaches and analytic thinking, characteristic of the left hemisphere, are fine in the right context, and may at a subsequent phase take part in creativity by narrowing things down and eliminating some of them, but on their own will not achieve creativity. And Asimov, Poincaré and Jobs all emphasise the making of (what to the left hemisphere seem to be) distant connexions.

This idea of a *broad* range is crucial. As Heraclitus put it, openness is required by the seeker of wisdom, as well as broad knowledge: ‘men who love wisdom’, he wrote, ‘must be good enquirers into many things indeed.’¹⁵ Interestingly, while the importance of a broad view is obvious when conceived in spatial terms, we forget that it also involves a temporal

element: integration of ideas from different periods of one's life, or even from different eras of history. When subjects were primed by asking them to think about the distant future, they subsequently did better on insight and creativity tasks; those asked to think about the near future did better on analytic tasks.¹⁶ The near in time is more predictable and under control, like whatever is physically 'under our thumb', and therefore more conducive to left hemisphere modes of thought.

For creativity to succeed, then, there needs to be *breadth of vision*; the capacity to forge *distant links*; *flexibility* rather than rigidity; a willingness to *respond to a changed or changing context*; as well as *tolerance of ambiguity* and of knowledge that is, at least at the outset, inherently *imprecise*.¹⁷ This all makes possible a quest for something that is truly new, not in the trivial sense of a 'novelty', but breaking out of the mould of the inauthentic, the stale and the familiar. And all this is terrain better traversed by the right hemisphere than the left, for reasons we have in part explored already, and will continue to explore. The right hemisphere not only preferentially deals with the new and unexpected, but also, as discussed, with the *unique*: generating unique rather than common responses shows 'greatest activation in the right temporal pole, which survived a whole brain multiple comparison.'¹⁸

The role of intelligence in relation to creativity has long been debated. However, it seems clear that creativity is closely linked to general intelligence.¹⁹ This is both in line with life experience, and with other related information we have: the ability to produce creative metaphors, for example, is strongly associated with fluid intelligence – and with the right hemisphere.²⁰ As we have seen, intelligence is, independently, more strongly associated with the right hemisphere than the left.²¹ Specifically, intelligence relates to creativity in two ways: there is a lower limit of intelligence compatible with creativity, which may be as low as an IQ of 85 for some kinds, and as high as 120 for others, or higher (about the level of an averagely performing undergraduate today). But creativity escalates with still higher intelligence:

creative achievement benefits from higher intelligence even at fairly high levels of intellectual ability ... This is in line with previous

studies reporting that IQ is predictive of creative achievement even within high ability groups.²²

PERMISSIVE REQUIREMENTS

A key component of creativity – one which researchers have not fallen over one another to claim – is serendipity: in other words our response to circumstances, not our capacity to alter them. People often seem to think that if you really understand the process of creativity, you will surely have many hot tips to offer on how to become more creative. (I am afraid these might be as useful as hot tips on how to become more intelligent or avoid Huntington's chorea.) But, be that as it may, the more you understand creativity, the less you will be inclined to imagine there are techniques for achieving it, even for those with any degree of aptitude.

We can't make creativity happen, but we can certainly do our best to stand in its way. Or therefore not. Furthering creativity is mainly about *not* doing, rather than doing. And in particular not doing any of the things that look obvious: trying hard, trying hard not to try, trying a systematic approach, trying a random approach, and so on. In fact trying anything at all. The creative process is inevitably governed by uncertainty, without which neither self-realisation nor creative innovation is possible. It can't be made to happen. Over-control is the enemy here as elsewhere. The less we leave things to fortune, the less likely we are to make a fortunate find. Once again one sees a conflict between the left hemisphere which sees its role as to control, and get things clear and fixed, and the right hemisphere which sees its role as to respond to the realities with which it is presented, and open up to potential. Though reason may be helpful at some stage, it can't *permit* creativity any more than it can *generate* it. It's best tactic is to back off for now.

The unwillable nature of creativity depends on the fact that the important processes are going on unconsciously, and, as the process progresses, are, at most, on the *fringes* of consciousness. And though you know it's on the fringe, because you have a feeling for what it is, the more you try to specify it prematurely, the more likely you are to get it wrong. At this stage trying hard to pin it down drives it further into the darkness. It has similar characteristics, on a large scale, to the 'tip of the tongue' phenomenon, on a small scale. If I forget a name while I am talking to someone, I feel obliged out of courtesy to cut the matter short by giving

them a clue – which is, however, often fatal. ‘Oh, you know, terribly famous German philosopher, name begins with a K – I’ll forget my own name next – come on, works are impenetrable – name *begins with a K*, I’m pretty sure.’ ‘Kant?’ ‘No, no – oh well, forget it.’ A minute later: ‘Damn it, Heidegger, of course!’ The only useful thing to do is to relax and to avert the mind’s eye. Then it will come of its own accord.

This is explicable at a neurological level, since both anxiety and narrowly focussed attention engage the left hemisphere, and each independently drives the other. The left hemisphere’s narrow-beam attention inevitably has its corollary at the neuronal level. The harder one tries, the more the left hemisphere recruits tightly knit arrays of neurones, which are part of what distinguish its structure, searching in the same area; like the man who was found searching for his keys, not where he had dropped them, but under the lamplight, because that was where he had enough light to search. Certain kinds of mind-wandering are creative;²³ narrow attention hampers creativity.²⁴ Only turning off the spotlight of left hemisphere attention enables the more complex and diffuse arrays of neurones in the right hemisphere to work on solving the problem.

And trying to see what has to be an unconscious process is like ‘trying to turn up the gas quickly enough to see how the darkness looks’, as William James memorably put it.²⁵

Here is Asimov again, this time on the permissive aspects of creativity:

My feeling is that as far as creativity is concerned, isolation is required. The creative person is, in any case, continually working at it. His mind is shuffling his information at all times, even when he is not conscious of it ...The presence of others can only inhibit this process, since creation is embarrassing ...

But if there are to be others involved:

First and foremost, there must be ease, relaxation, and a general sense of permissiveness ... a feeling of informality ... a meeting in someone’s home or over a dinner table at some restaurant is perhaps more useful than one in a conference room. Probably more inhibiting than anything else is a feeling of responsibility. The great

ideas of the ages have come from people who weren't paid to have great ideas, but were paid to be teachers or patent clerks or petty officials, or were not paid at all. The great ideas came as *side issues* ...²⁶

‘Side issues’: remember that all the really valuable things in life defy pursuit, but come unbidden when we are looking elsewhere.

Preconceptions hamper the generation of solutions since they easily turn into constraints.²⁷ Consequently, one of the ways to encourage flexibility is the relaxation of self-imposed constraints.²⁸ And, most importantly, the adoption of the stance of someone who does not know, and is prepared to listen. Those who are creative do not know their outcomes in advance, even though some idea of a purposive goal may exist.²⁹ As George Steiner puts it, speaking eloquently of Heidegger:

As knower and user, the *ego* is predator. For Heidegger, on the contrary, the human person and self-consciousness are *not* the centre, the assessors of existence. Man is only a privileged listener and respondent to existence. The vital relation to otherness is not, as for Cartesian and positivist rationalism, one of ‘grasping’ and pragmatic use. It is a relation of audition. We are trying ‘to listen to the voice of Being’. It is, or ought to be, a relation of extreme responsibility, custodianship, answerability to and for.³⁰

TRANSLATIONAL REQUIREMENTS

While these first two requirements, the *generative* and *permissive*, need to be present together, to some extent the third, *translational* element can be postponed. It depends on the business of seeing how to carry through an insight to completion. The same daring that, according to Asimov, is needed to make the connexion, is required to make something out of the insight – together with a good deal of perseverance. On attitudes to originality, especially in science, Ghiselin astutely comments:

men have developed their conservatism as a necessary guard against the dispersal of the order they live by. Whatever the cause, the tendency to distrust the widest and freest ranging of the mind is so strong that the changes necessary for the development of human life could not be attained without the efforts of the more daring and ingenious of mankind.³¹

But, as Poincaré remarked, ‘how is this faculty to develop, if, as soon as it shows itself, it is hounded out and proscribed, if we learn to distrust it before we know what good can be got from it?’³² The main qualities that help in this phase are courage in the face of discouragement, persistence, and a capacity to pursue one’s end rationally. This is, at last, where the rationalising analytic mind plays a part in creativity.

There is a phenomenon I call ‘left hemisphere chauvinism’, the tendency to discredit the role of the right hemisphere, since its methods are less predictable and potentially programmable than those of the left hemisphere, and thereby represent an affront to the narrower type of scientific mind. The right hemisphere used to be thought of as primitive, unintelligent and ‘coarse’ in its processing, because we can’t understand it so well; and a poor second to the sophisticated, intelligent and ‘fine’-processing left hemisphere – which we can. This is suspiciously like looking in the mirror and admiring what you see. It’s a point of view that is slowly dying out, but you still hear it among the diehards. And one of the myths that really irritates some neuroscientists is that there is something

special about the role played by the right hemisphere in creativity. It really seems to get right up their noses.

I know why, too – at least I know another reason why. It's not *just* that, for all except the best scientists, creativity is not their strong suit. They have got where they are by being good at following procedures, not by seeing when and how to transcend procedures. It's not *just*, either, that they have an antipathy to what Freud called primary processes, those that are unconscious, implicit and hidden from the light of day, and wish to turn them all into processes that are conscious, explicit and manipulable. It's that there is a lot of simplistic guff talked about the topic, as there is about everything to do with hemispheres.

One of the things that neuroscientists assert is that both hemispheres are involved. Well, that's easy: *of course* they are. It is inevitably the case that creativity will involve both hemispheres at some point – because absolutely everything does, just in a different way. That said, there is also a naïve belief among a few neuroscientists that that is the end of the matter. It fairly clearly isn't. The existence of popular misconceptions doesn't excuse us from evaluating the situation more fairly.

Just about everything that is said about the hemispheres in pop psychology is wrong because it rests on beliefs about *what* the hemispheres do, not about *how* they approach it: each does so in a consistently different way. And mainstream science commits the same solecism, trying to work out what each hemisphere 'does': finding they are both involved in everything, it tends to conclude that there is no difference. That conclusion is at variance with that of pop psychology, but is just as misguided, for similar reasons: it starts from the same mistaken premise: that it's the *what*, not the *how*, that matters.

Creativity is less a 'what', a thing that is done, than a manner in which whatever it may be is approached. It is not an entity, but a disposition towards the world. You can use language, engage in mathematics, draw, design, build, or compose creatively or uncreatively. Given the importance of the 'how', there is a high chance that the hemisphere's approaches will not be equally creative. And they are not.

There is nothing, in one sense, that I would like better than to be able to report that there is no lateralising element in creativity. What a relief that would be! It would earn the easy applause of my colleagues rather than the obloquy I invite. It would be a comfortable conclusion. But it simply

wouldn't be true. There is a huge and rich literature from many types of sources which finds, if nothing else, the so-called 'divergent' element in creativity to be strongly linked to the right hemisphere. And the 'divergent' element isn't all, as we shall see. Where there are rules and procedures to be followed, the left hemisphere is in its element; where there aren't, it is lost.

Creativity is one of those areas where there just aren't rules and procedures. Rule, and regulation, come from the same Proto-Indo-European root *reg-*, the meaning of which is to move in a straight line (a ruler is a tool for drawing straight lines). Creation is the business of the irregular. Even creative mathematical thinking is a matter of insight, almost always visual, *Gestalt* perception – pattern recognition, something at which the right hemisphere excels, but the left hemisphere does not understand. Only later is it re-formed according to rules, sequential procedures, left hemisphere fashion. Broadly speaking, the right hemisphere plays the role of opening up to possibility, making analogies and connexions, and the left hemisphere that of regularising, and closing down to (what it takes to be) a certainty, so that, as much as possible, what first came as a gift can be made serviceable, and called upon whenever required at will.

Thus in creativity there are bound to be at least, and at the very simplest, two phases, that may often nonetheless overlap: a phase of exploration guided by the imagination; followed, at a distance of anything from seconds to months, but in any case *followed*, by a critical sifting and evaluation of the results. Analytic, critical, convergent thinking must have something to work on: you can't think critically without something to criticise, or narrow down the field without having a field to narrow. To quote the philosopher Bryan Magee: 'Reason can be used to tear apart bad arguments and it can be used to apply universal principles to particular cases. But reason as an instrument of analysis on its own is uncreative.'³³ Or, as Schopenhauer put it succinctly: reasoning 'can give only after it has received'.³⁴

Here again is Poincaré the mathematician talking about the true scientific method, not the one you hear about at school:

It is by logic that we *prove*, but by intuition that we *discover*. To know how to criticize is good, but to know how to create is better ... Logic teaches us that on such and such a road we are sure of not meeting an obstacle; it does not tell us which is the road that leads to

the desired end. For this it is necessary to see the end from afar, and the faculty which teaches us to see is intuition. Without it, the geometrician would be like a writer well up in grammar but destitute of ideas. ³⁵

Reason cannot be the creative principle, unlike intuition: it is the quality control department only. 'Since a test is in its very nature of a negative character', wrote John Henry Newman, 'and since argumentative forms are mainly a test of reasoning, so far they will be but critical, not creative. They will be useful in raising objections, and in ministering to scepticism; they will pull down, and will not be able to build up.'³⁶

Newman was a philosopher: surely philosophy is done by pursuing logical procedures? Not necessarily so at all. Descartes' name is synonymous with logical rigour: famously his philosophy came to him one day while, an enlisted soldier, he was resting in, on, or near (according to varying accounts) a large Bavarian stove. Apparently he received suddenly 'answers to tremendous problems that had been taxing him for weeks. He was possessed by a Genius, and the answers were revealed in a dazzling, unendurable light.'³⁷ At any rate he underwent an '*enthousiasme*', a word which preserved its original and literal meaning of possession by a god (Greek, *en theos*); and experienced three visionary dreams, believing that a divine spirit had revealed to him his new philosophy.³⁸ 'It is notorious that a philosophy is not made, it grows', wrote Waismann:

Whoever has pondered some time over some dark problem in philosophy will have noticed that the solution, when it comes, comes with a suddenness. It is not through working very hard towards it that it is found. What happens is rather that he suddenly sees things in a new light – as if a veil had been lifted that screened his view, or as if the scales had fallen from his eyes, leaving him surprised at his own stupidity not to have seen what was there quite plain before him all the time.³⁹

Although it has become unpopular to see creativity as a gift, rather than something democratically achievable by anyone by dint of application, the truth is we cannot make ourselves poets: *poeta nascitur, non fit*, a poet is

born, not made. Similarly we do not put a poem, or any other work of art, together. It is not assembled from pieces, left hemisphere fashion, but conceived whole, right hemisphere fashion. 'A work of art is a unit *originally*,' wrote Susanne Langer, 'not by synthesis of independent factors. Analysis reveals elements in it, and can go on indefinitely, yielding more and more understanding; but it will never yield a recipe.'⁴⁰ Goethe as usual had the measure of it:

I can certainly put together the individual parts of a machine made of separate pieces, and, upon such a subject, speak of composition; but not when I have in my mind the individual parts of an organic whole, which produce themselves with life, and are pervaded by a common soul ... How can one say, Mozart has *composed Don Juan*! Composition! As if it were a piece of cake or biscuit, which had been stirred together out of eggs, flour, and sugar! It is a spiritual creation, in which the details, as well as the whole, are pervaded by *one* spirit, and by the breath of *one* life; so that the producer did not make experiments, and patch together, and follow his own caprice, but was altogether in the power of the dæmonic spirit of his genius, and acted according to his orders.⁴¹

Creativity, as agreed, is enormously difficult to study and the elements used to simulate it in experimental settings are only tenuously connected with how the mind actually works in creative moments. Brainstorming, for example, is, practically, the antithesis of creativity, since creativity is not 'willed', nor a matter of senseless, random forays into the unknown. There is no formula for being creative. It is something that comes to us from our unconscious mind at a moment we cannot force or predict (which doesn't mean it happens without the mind being 'prepared'); and it is by no means random, but guided by intuited shapes that are only partly seen. The point has been made many times, that if mathematicians, or scientists, or chess players, or poets, or artists, or composers had to consider methodically all the possibilities, there would not be enough time in the history of the universe. In reality only a very limited number of self-selecting forms present themselves, vaguely at first, and more clearly as the business of

creation continues, more like a picture gradually coming into focus than the following of steps towards a goal. According to Poincaré:

[creative] mathematical work is not simply mechanical ... it could not be done by a machine, however perfect. It is not merely a question of applying rules, of making the most combinations possible according to certain fixed laws. The combinations so obtained would be exceedingly numerous, useless and cumbersome. The true work of the inventor consists in choosing among these combinations so as to eliminate the useless ones or rather to avoid the trouble of making them, and the rules which must guide this choice are extremely fine and delicate. It is almost impossible to state them precisely; they are felt rather than formulated ... the subliminal self is in no way inferior to the conscious self; it is not purely automatic; it is capable of discernment; it has tact, delicacy; it knows how to choose, to divine. What do I say? It knows better how to divine than the conscious self, since it succeeds where that has failed. In a word, is not the subliminal self superior to the conscious self? ⁴²

We are drawn forwards towards some scarcely perceptible form in the surrounding obscurity, towards something we intuit is *already there*; not just propelled, as it were blindly, and from behind, by a chain of causation that has to run through all the possibilities to find one that works. That's what a computer does. It's not how the human mind works. And since creativity can never be divorced from the business of existence, which is also a continual coming into being, it is, I suspect, relevant that this is an analogy of what we are now coming to realise about natural selection, that it cannot possibly rely on purely random mutations, but must act on a self-selecting group of possibilities. I will have more to say about this in Chapter 12.

It would be tempting, but wrong, to see artistic creativity as a *necessarily* superior process in this respect, science having been relegated to purely mechanical, assembly line procedures.

Here is one of the greatest scientists of the last century, the biologist, Sir Peter Medawar:

Every discovery, every enlargement of the understanding, begins as an imaginative preconception of what the truth might be. The imaginative preconception – a ‘hypothesis’ – arises by a process as easy or as difficult to understand as any other creative act of mind; it is a brainwave, an inspired guess, a product of a blaze of insight. It comes anyway from within and *cannot be achieved by the exercise of any known calculus of discovery.*⁴³

Remember those last words when we come to consider the pronouncements of the students of the school of ‘Nothing But’-tery.

It might be thought that, while great works of art are the result of being able to see a whole structure or form from the outset – creation being the process of progressive precipitation into reality – science was altogether a different matter. Not so: Konrad Lorenz wrote eloquently about how a new scientific insight comes about. He starts with a reflection on the strange antipathy towards *Gestalt* perception among scientists, despite the dependence of science on perception by sense organs – a process that is already highly selective, interpretive and responsive to pattern:

It is one of the tragic-comical paradoxes of perverted scientific fashion that it is necessary to *legitimize* a procedure in the eyes of men who unavoidably use it in their daily work. Perception is the first step in any process of gaining knowledge of outer reality ... It is the sense organs, to which the physiological mechanisms belong, which, by complicated and non-conscious computations, abstract perceptions out of the chaos of innumerable sensory data.

And he continues:

Of myself, for one, it is simply not true that my first step in approaching any phenomenon I have observed consists in creating a rather random hypothesis and subsequently trying to find fault with it. Knowing about the functions of my perception as I do, I feel inclined to suspect that the sequence of events is, at least partly, the reverse of this. I strongly suspect that, at the time when a set of phenomena seriously begins to fascinate me, my *Gestalt* perception

has already achieved its crucial function and ‘suspected’ an interesting lawfulness in that particular bunch of sensory data. If I then spend more and more time in observation of these particular phenomena, it is already a consequence of a hypothesis which my perception has formed, though I may still be quite unconscious of it.

He carries on to describe how, as a consequence of amassing more and more data, the ‘perceived lawfulness’ or formal structure, the *Gestalt*, ‘detaches itself from the background of accidentals’, and there is an ‘aha’ moment of insight; and concludes that, in the absence of unconscious promptings,

if our conscious effort at cognition really had to start at the level of miscellaneous, unprocessed sensory data – we really should have to approach them with nothing but a consciously built-up hypothesis, as yet unsupported by any factual evidence. Inductive procedure would, I think, really be impossible and it would indeed be the best strategy of research to do one’s best to disprove a hypothesis which, in this case, would be highly unlikely to contain any appreciable amount of truth. *Gestalt* perception, on the other hand, when based on a sufficient wealth of unbiased observation, has a way of being *right*, and if one is familiar with its occasional trick of being altogether wrong and knows when to discount its assertions, it is an invaluable and quite indispensable guide. ⁴⁴

Most interesting to me is the place of time in the process: not a route march into the randomness of chaos, propelled forward by arguments that are consciously conceived, therefore by something in the past, annexing territory as one goes, but rather, after paying appropriate attention over long periods of time, being drawn forward towards something in the future, unconsciously perceived. In this connexion, a reported conversation between Max Wertheimer, the founder of *Gestalt* psychology, and Albert Einstein, about the latter’s thinking, is illuminating:

Einstein said: ‘These thoughts did not come in any verbal formulation. I very rarely think in words at all. A thought comes,

and I may try to express it in words afterward'... I once told Einstein of my impression that 'direction' is an important factor in thought processes. To this he said, 'Such things were very strongly present. During all those years there was a feeling of direction, of going straight toward something concrete. It is, of course, very hard to express that feeling in words; but it was decidedly the case, and clearly to be distinguished from later considerations about the rational form of the solution.'⁴⁵

THE ROLE OF THE RIGHT HEMISPHERE

Insights

As mentioned, there are voices that deny the special role of the right hemisphere in creativity. I will turn to them directly in due course. Meanwhile, how strong is the evidence that the right hemisphere plays, if not the only role, at any rate the crucial role in creativity?

Before I go further, let me state very clearly that my intention is not to ‘reduce’ creativity to its brain correlates, nor to find a ‘mechanism’ for creativity, nor to suggest that there is a simple, localisable creativity ‘centre’ in the brain. It is to compare two living systems fundamental to being human, those of the right and left hemisphere, and ask the perfectly legitimate and interesting question whether there are differences in the way and the degree that each is involved in creativity.

A descriptive study based on published accounts by 120 subjects of their ‘aha’ moments yielded some interesting insights into insight:

Virtually all insights involved a change in understanding ... a surprising number of insights were triggered by inconsistencies and contradictions. The insights that were triggered by contradictions seemed to depend on the person taking the anomalous data point seriously rather than attempting to explain it away ...⁴⁶

The left hemisphere’s inclination, as Ramachandran observed, is to preserve the model at all costs, dismissing an anomaly; the right hemisphere again, according to Ramachandran, is the ‘anomaly detector’, the ‘devil’s advocate’.⁴⁷

I have already referred to the principle that the right hemisphere makes more connexions, but this has truth at the most literal, concrete level. I have drawn attention to macroscopic asymmetries of the brain, but spent less time exploring fascinating asymmetries at the microscopic, cytoarchitectonic level (that of the arrangement of cells), which have major consequences for how each hemisphere ‘sees’ the world.⁴⁸ Neurones make

contact through synapses on branches called dendrites. In areas of association cortex such as the anterior temporal cortex, right hemisphere pyramidal neurones have more synapses overall, and especially more synapses far from the cell body, than those of the left hemisphere. What this means is that they make *not only more connexions overall, but connexions over a far larger area.*⁴⁹ This in turn means that the areas connected are more differentiated one from another, and that there will be a variety of types of communication going on. This contrasts with the left hemisphere's 'smaller input fields', which 'collect highly similar inputs, likely causing the neuron to respond best to somewhat redundant inputs'.⁵⁰

On first principles one would expect insight to depend heavily on the right hemisphere. Just look at what it involves: seeing the problem in a new way; connecting the problem to another that has the same structure; seeing patterns and permitting constant revision of one's mental model; seeing the problem in a broader context; making connexions between apparently remote ideas; allowing unconscious processing outside the spotlight of attention; parallel interactive processing, not serial processing, involving holding together a number of different strands of thought at the same time and integrating them into a complex new pattern rather than progressing by securing one's steps one at a time; spotting the anomaly in the current picture and not just ignoring it; accessing past experience that is relevant and letting go of memories that are impeding a solution; freedom of the unconscious from constant over-riding by conscious thought processes, and a conscious mind more open to its promptings. All these reflect aspects of brain function at which the right hemisphere is more adept than the left.

Intuition could also be thought of as the synthesis of experience with unconscious reasoning on the basis of that experience. The left hemisphere will have its intuitions, but they are likely to be misguided: the right hemisphere is more likely to be a source of good intuitions than the left because it is (1) more in touch with autobiographical memory and personal experience;⁵¹ (2) more in touch with the body and emotion;⁵² (3) better able to regulate emotion;⁵³ and (4) better able to stand apart from bias.⁵⁴ So, to that extent, intuitive insights can be identified with the right hemisphere.

Incidentally, higher intelligence has also been found to be associated with better performance on insight problems,⁵⁵ and it has been shown to be associated with the ability to solve British-style cryptic crossword puzzles, which depend on making remote associations, radically shifting

perspective, and ignoring the literal and obvious.⁵⁶ Solving such puzzles is full of ‘aha’ moments, the pleasure of which is the main reason for doing them. As we have seen, creativity, too, is linked to intelligence; and in general the right hemisphere is of more critical importance to intelligence than the left.

What do we know, from direct inspection, about the brain correlates of ‘aha’ moments? One of them is, precisely, their robust association with right hemisphere activity. When subjects try to solve classic insight problems, they benefit more from hints flashed subliminally to the left visual field (ie, the *right* hemisphere) than from hints similarly presented to the right visual field (ie, the *left* hemisphere).⁵⁷ Differences in brain activation in the left and right hemisphere seem to be indicative of insight versus non-insight solutions: ‘the right hemisphere plays a unique role in insight’.⁵⁸ In particular, the right (but *not* left) frontal and parietal regions are strongly associated with the actual (‘aha!’) moment of recognition.⁵⁹ By contrast, during serial search solutions – the way a computer would have to work – the right prefrontal cortex is either not activated, or may be specifically *de*-activated.⁶⁰

Other work suggests the importance of part of the insula, an area closely involved with the frontal cortex, and again particularly on the right.⁶¹ Even verbal problems, which classically engage the left hemisphere more than the right, rely on the right hemisphere if they require insight.⁶² We saw in Chapter 4 that functional magnetic resonance imaging reveals increased activity in the right anterior superior temporal gyrus when an insight solution occurs: this same right anterior temporal area is associated with making connexions across distantly related information during comprehension.⁶³ EEG studies confirm this finding: moments of insight are associated with a burst of gamma waves over the right temporal lobe and with activity in the medial aspect of the right anterior superior temporal gyrus.⁶⁴ These findings have been repeatedly replicated: according to one study, ‘the same network of areas all far exceeded critical statistical threshold, with the right anterior temporal region again being the strongest’.⁶⁵ A burst of alpha activity has also been observed over the right occipital cortex, just before the moment of insight is experienced.⁶⁶ This may be related to the suppression of external visual input:⁶⁷ for more detail see Appendix 1. According to Kounios and Beeman,

outwardly directed attention coupled with low anterior cingulate activity focuses processing on the dominant features or possibilities of a situation; inwardly directed attention and high anterior cingulate activity heightens sensitivity to weakly activated remote associations and long-shot solution ideas.⁶⁸

The brain correlates of solving Chinese *chengyu* riddles were observed while subjects used either conventional analytic approaches (not involving insight) or insight solutions: in insight, there was greater functional connectivity between the right inferior frontal gyrus and right middle temporal gyrus (both areas already known to be involved in insight), supporting, according to the authors, ‘the right-hemisphere advantage theory of insight.’⁶⁹ In cases where both hemispheres begin the process of problem-solving, it quickly becomes only the right hemisphere that sustains and maintains the process.⁷⁰ Once again, unconscious cues flashed to the left (the right hemisphere’s) visual field, but not those flashed to the right (the left hemisphere’s) visual field, resulted in moments of insight. These right hemisphere advantages occur only when solvers experience insight – the ‘aha!’ or ‘eureka!’ feeling.⁷¹ And all of this ties in with what we have already learnt about the importance of visual thinking, since the right lateral prefrontal cortex is also active in problem-solving using visualisation.⁷²

Literature reviews have generally concluded that the right hemisphere is dominant for the processes associated with creativity.⁷³ In a series of studies, Friedman and Förster investigate the effect of approach and avoidance cues on hemispheric activation, creativity and analytic problem-solving. Their findings suggest a relationship between approach motivation and global thinking; approach motivation and creative thinking; avoidance motivation and local thinking; and greater relative right hemispheric activation both in approach motivation and in better performance on creativity tasks.⁷⁴ A meta-analysis of 88 studies in the creativity literature by Konstantin Mihov and colleagues reported that ‘researchers of the lateral dominance have, with fair certainty, come to the conclusion that the right hemisphere and its regions are specialized for creative tasking’.⁷⁵ The authors point out that a *global* thinking style, a *context-sensitive* thinking style and a *figurative* style are each known to be involved in creative

thinking, and that each of these is, on its own, significantly more likely to involve right hemisphere dominance.

In fact the authors of this review found that a primary role for the right hemisphere was to be found regardless of whether tasks were figural or verbal, holistic or analytical, context-dependent or context-independent. They found that local processing – as has been often noted – may also be carried out at least to some extent in the right hemisphere, and that the right hemisphere contribution during global processing may be much stronger than the left hemisphere contribution during local processing. They conclude:

The systematic meta-analytic approach of our review found that in the literature covering various techniques for assessing lateral dominance and creativity, there is a consistently reported right dominance.

To make assurance doubly sure, they treated studies that showed no hemisphere difference as, instead, showing left activation only (ie, working against their main hypothesis). Even this could not ‘over-ride the effect of right hemispheric dominance’, despite, moreover, the fact that a ‘large number of the creativity tasks are in fact lexical in nature’.⁷⁶ Even studies specifically looking at a creative task that is verbal in nature – such as solving verbal problems using insight – show that they benefit from right hemisphere semantic processing, particularly again in the right anterior superior temporal gyrus.⁷⁷ And, *a fortiori*, one would expect, and one finds, that *non-verbal* problem-solving recruits largely right, rather than left, hemisphere activation.⁷⁸

Naturally, the evidence considered includes much that comes from imaging and EEG studies, which are not always easy to interpret. This is where the lesion studies – which tell us what happens to creativity when something happens to a particular area of the brain – are particularly valuable as guides to interpretation. What do they show?

HEMISPHERIC CONTRIBUTIONS TO CREATIVITY IN GENERAL

I will begin by looking at lesion studies in the general population: they provide clear evidence of the relation between the right hemisphere and originality. Patients with focal strokes in the left prefrontal cortex have been shown to outperform normal participants in creative problem-solving tasks that require breaking away from rule-based thinking.⁷⁹ According to a survey by Simone Shamay-Tsoory and colleagues, lesions in the left temporoparietal region, known to be involved with language processes, are associated with higher levels of originality, and the larger the lesion in this area, the greater the originality. The left frontal lobe may inhibit the right hemisphere during figural creative thinking in normal people, and removal of this inhibitory effect by practice or by 'specific damage to the left frontal lobe' may facilitate the emergence of artistic creativity. On the other hand, those with lesions in the right prefrontal cortex show 'the most severe impairments in originality'.⁸⁰ It is probable, as they suggest, that the more linear cognitive style of the left hemisphere, suited to its manner of language processing, interferes with creativity.⁸¹

Further, a survey of nearly 70 patients with frontotemporal dementia indicated that patients with enhanced artistic creativity showed selective degeneration of the temporal lobes, in particular a left hemisphere perfusion deficit. In nine out of 12 cases where creativity increased with the onset of dementia, the temporal pathology was worse on the left, in two cases on the right (one of which was a left-hander), and in one case the degeneration and perfusion deficits were considered symmetrical.⁸² Mario Mendez, a neurologist at UCLA, deduces from a study of dementia that artistic expression depends in particular on the right dorsolateral frontal cortex for original, divergent thinking, and suggests that 'the left parietal region and the left temporal lobe have inhibitory effects on artistic expression through attention to visuo-spatial *detail* and semantic labelling, respectively.'⁸³ Already we can see three reasons why the left hemisphere will present problems for creativity: it is too linear, too detail-focussed, and too concerned with naming or labelling, which tends to crystallise meaning prematurely.

A note on detail: there is a difference between detail-focussed attention, and attention to a whole which causes an anomalous detail to stand out. The first starts from details and never arrives at a *Gestalt*, thus missing the significance of an anomaly; the second starts with a *Gestalt*, the very existence of which draws attention to the detail that does not fit. Such a perception may cause the *Gestalt* to shift: a creative discovery. Details are not unimportant, but their significance becomes apparent only when taking in the whole. And, as Ramachandran puts it, the right hemisphere is our anomaly detector.⁸⁴

The role of flexibility in both intelligence and creativity is important, and the critical role of the right ventral prefrontal cortex is reinforced by a study of 53 patients with focal brain lesions compared with normal controls, showing that patients with focal right prefrontal cortex lesions were specifically impaired in tasks that required flexibility in set-shifting, an important component of divergent thinking.⁸⁵ Right brain-damaged patients, as another study demonstrates, show more repetitive (inflexible) behaviour than patients with comparable lesions in the left hemisphere.⁸⁶ A further study confirms that right hemisphere injury impairs flexibility of thinking and results in people becoming 'stuck in set'.⁸⁷

In a study of 60 patients with focal brain damage compared with matched controls, the right prefrontal cortex was seen to have a critical role in 'open-ended' tasks, a sign of the right hemisphere's greater ability to plan ahead, remain flexible and deal with incomplete information.⁸⁸

A detailed case study of an architect, not just carrying out typical lab tests, but doing what he was used to doing in real life, is instructive. The architect, who had developed a lesion in the right prefrontal cortex, was examined by neuroscientists Vinod Goel (who incidentally himself first trained as an architect) and Jordan Grafman.⁸⁹ They gave him a real-world architectural planning task: to develop a new design for their lab space. And they compared his performance on the task with that of another architect called in for the purposes of the experiment. The patient understood the task, observing that 'this is a very simple problem' (it is highly characteristic of individuals with right, but not left, hemisphere lesions grossly to overestimate their capacity in relation to the task).⁹⁰ He hadn't, apparently, lost any of his fund of architectural knowledge, and he was able to draw on it appropriately while structuring the problem. However,

although he could structure the problem in the abstract, he couldn't take the next step to solving it: as a result he did not start even his preliminary design until two-thirds of the way into the experiment. When he got round to it, the preliminary design was 'minimal and erratic, consisting of three independently generated fragments', and there was no progression of these fragments towards a meaningful whole. Abstract, theoretical information was not carried over into the creation of a design.

There are a number of aspects of the case of this architect that might be expected as a consequence of a right frontal lesion. I have mentioned the lack of insight into his capacity and the unawareness of his deficit; but there is also a characteristic inability to get from broad general abstractions to dealing with the real world of concrete experience; an inability to create a meaningful whole, instead producing 'erratic' fragments; and a failure of creative imagination.

Turning from the general population, what can we learn from *artists* who develop lesions? This area is admittedly not straightforward for a number of reasons. One is that creativity is hard to separate out when many brain changes occur simultaneously: for example, has the subject lost creativity, or just the practical means of expressing it? Or the will to do so? Are the problems technical – visuo-spatial distortions only, loss of manual dexterity only – or to do with creativity itself?

In the case of a left hemisphere stroke, an almost invariable problem is the loss of use of the painting hand. One might be forgiven for thinking this a catastrophe. Imagine being a great painter and suddenly having to struggle to paint precisely, delicately, fluently, naturally, by using your non-dominant hand! It is, frankly, astonishing that any regain their flair at all. Yet the evidence is that it is easier to compensate for this fairly massive motor control handicap than for the visuo-spatial handicaps of right hemisphere stroke: visual neglect, loss of depth, loss of flow, loss of the *Gestalt*.

Nonetheless, it is quite true that such losses are not indices of loss of creativity *per se*. And then there is the confusing fact that taste in modern art is more receptive than usual to elements that are visuo-spatially bizarre or distorted, something far more likely after a right hemisphere stroke, and may even celebrate such elements as signs of 'creativity'. Many elements to be found in modern art are, in fact, strikingly similar to distortions experienced in right hemisphere damage.⁹¹ So, when styles are thought to

deteriorate after right hemisphere stroke, it is not necessarily a sign of loss of creativity; and, on the other hand, when they meet with applause, this may not be a gain in creativity either, because they may simply be fashionably dysfunctional.

Nonetheless, there is some evidence that creativity is more commonly impaired by right hemisphere stroke than left.

Artists

After a right hemisphere stroke, a prominent Polish artist and sculptor, Krystyna Habura, complained that she had lost her artistic vision. She said that it was as if she had a 'hole' in her brain (she had), and could not paint.⁹² In another case, Armin Schnider and colleagues write that

our patient's post-stroke drawings were clearly different from premorbid works: spatial arrangement was disturbed by left-sided neglect, he produced no oil paintings any more, and his drawings were usually finished within 10–15 minutes, leaving them less elaborate than his premorbid efforts ... [His drawings] now appeared simplified, more sketch-like, even though the character of the lines and the compositions were similar.⁹³

Fig. 20. Drawing of a cyclist by the same artist before and after right hemisphere strokes (adapted from Schnider et al 1993)

In an interesting paper, Olaf Blanke and Isabella Pasqualini compare what happened to a famous German painter, Lovis Corinth, and the film director Luchino Visconti, following right hemisphere strokes.⁹⁴

Corinth's stroke came in 1911, at the age of 53: art critics make a sharp distinction between his mature impressionist, pre-stroke style, and his post-stroke, possibly expressionist, style. The art critic Alfred Kuhn, writing in the year of Corinth's death, described how after the stroke 'the preponderance of the plastic and corporeal starts to disappear progressively', and pictures become 'essentially plane-like': 'the contours disappear, the bodies are often as if pulled apart, deformed, their spatial relationships distorted', as if this were no longer important to Corinth. This is in stark contrast with Corinth's pre-stroke style that made him famous, which was characterised by high levels of corporeality, the rich nuances of human flesh, and the beauty of depth and spatial relations between objects, people, and their environs.⁹⁵ Anna Mazzucchi and colleagues write:

His [post-stroke] paintings are flat and rather elementary with hardly any tri-dimensionality. There is imbalance between the right and left portions of the canvas, chromatic impoverishment ... Later on, starting in 1921, his left-side neglect becomes again obvious, together with further deterioration of his chromatic sense. Figures are flat, simplified, and at times hard to distinguish. There is a marked imbalance between the left and right side of the painting and decreased capacity to mask these problems.⁹⁶

The director Visconti's stroke came in 1972, when he was 65. His style changed dramatically. In the first place, it shifted from a spatiotemporally 'realistic' perspective induced by filming the entire scene sequence within the real location's limits (location filming with few close-ups mostly embedded into large filmic panoramas and the use of cross-fades), to a constructed 'space of glances' by frequently deployed sequences of close-ups and more static perspectives.⁹⁷ Second, this was associated with topographical and architectonic spatial disruptions, by contrast with his celebrated clarity of cinematographic space. Third, in the post-stroke films the actors much more often face the camera frontally, generating the impression of flatness of bodies and scenery, compared to the pre-stroke

films where perspectival changes as well as richness and clarity of space and figures are more prevalent, and render a more complex spatial configuration.⁹⁸ The film critic Geoffrey Nowell-Smith writes that ‘the last two films (*Conversation Piece* and *The Innocent*) were curious and puzzled his admirers as much as his detractors’.⁹⁹

There is in both Corinth and Visconti, the paper’s authors suggest, a flattening – what they call a ‘plane-like’ style – a spatial dislocation and a sense of stasis. These are all recognised consequences of right hemisphere damage.

Anton Räderscheidt was a German artist who emigrated to France in his 40s. In his earlier work he adopted a rigid, deliberately stiff, cold, achromatic style. He abandoned this style after emigrating, and his pictures became much livelier, more fluid and more colourful over the next thirty years to his death. At the age of 75 he had a right hemisphere stroke. After this he painted what he himself called his ‘nasty paintings’ (*böse Bilder*); his biographer Herzog calls them ‘acompository’, and says, that the physiognomy of the figures is ‘disfigured beyond recognition’. Of his stroke Räderscheidt said:

A stroke has taken me away from the scene of life ... I am no longer the director of this play. I have to take care, not to miss my entrance in the play. My requisites obey to tricks only. Moreover, I am missing my loud colours ... The reproduction of my surroundings is a damned difficult thing. Nothing is staying in its place, nothing is keeping the shape...¹⁰⁰

It has been suggested that his post-stroke paintings are more lively, less stiff, but, as Richard Jung says, ‘although the immobility of the earlier pictures is relinquished, this change of style is not attributable to disease, since similar representations began some years before the stroke.’¹⁰¹ Indeed they can be seen quite consistently some 20–30 years before the stroke.

Otto Dix was a well-known German painter who was severely censured by the Nazis as ‘degenerate’. In 1967, aged 76, he suffered a stroke due to a thrombosis of the right middle cerebral artery. He soon resumed painting again, until 1969 when he suffered another massive stroke and died. Following his first stroke,

there appeared an obvious lack of co-ordination between volumes and space ... the figures appear drawn in very summary fashion, strictly bi-dimensional, drawn using very elementary colors without any attempt to fuse the various parts of the painting which appears globally incoherent ... a series of deficits resulting in marked simplification added to evidence of a striking visuo-spatial disorder.¹⁰²

Plate 7 shows five self-portraits by Dix from before and after his stroke. Of particular interest is that in drawing (*f*) his right hand, holding the pencil, has obtruded into the picture and obscures a large part of the face. This hand also has six fingers (as it does in the last of his large post-stroke self-portraits, with his grand-daughter Marcella, painted in 1968 or 1969).¹⁰³

As an aside, it is curious that, for no obvious reason, Visconti's right hand is seen in the opening credits for *The Innocent*, his last film. Two phenomena may be involved here. It may be that in the absence of counterbalancing input from the right hemisphere, the right hand, the left hemisphere's tool, bulks large in the subject's world, becomes intrusive and obtrusive. And there may be a conflation of levels, leading to self-reference – a feature of left hemisphere cognitive style – so that the very hand that depicts becomes the object of depiction. The medium has lost its translucency and become opaque.

A paper by Bänzner & Hennerici describes 13 artists who had a right hemisphere stroke, of whom the authors say

the stroke influences the painting in the vast majority of artists to a relevant degree. Whereas in some cases the stroke ended the artistic career (Fellini), the majority of the painters reported resumed artistic production although they had to overcome various degrees of disability ... [including] severe visual disturbances ... Degrees of neglect can be inferred from the post-stroke artwork of virtually all of the right-hemisphere patient-artists ... [and] facial distortion in at least 6 of the right-hemisphere patients.'¹⁰⁴

Note that these cases are referred to not as exhibiting a new lease of life in the painter, but as presenting problematic distortions that might or might

not be overcome. So not a clear loss of creativity, granted; but not a clear indication that there is no such loss, either.

In the case of two other artists with a right hemisphere lesion, painting became reportedly naïve and concrete in one,¹⁰⁵ but in the other produced a rich output with excellent spatial organisation of the drawings, which goes to demonstrate that prognostication is not straightforward.¹⁰⁶

Strokes in the left hemisphere, on the other hand, despite the overwhelming motor difficulties involved, tend to leave artistic talent untouched, and in some cases even enhanced.¹⁰⁷ The great French neurologist Théophile Alajouanine knew several artists so afflicted. Of one artist, now known to be Paul-Élie Gernez, he wrote that ‘artistic realization in our painter since his aphasia remains as perfect as before. According to connoisseurs, he has perhaps gained a more intense and acute expression ... In him the aphasic and the artist live together on two distinct planes.’¹⁰⁸

Daniel Vierge, a Castilian painter, suffered a serious left hemisphere stroke at the age of 31, resulting in right-sided paralysis, with the result that he had to change his working hand. Undaunted, he carried on painting, drawing and engraving and six years after his stroke, in September 1889, won first prize at the Universal Exposition in Paris. His series of drawings for an edition of *Don Quixote* published in 1906, was, according to the writer Rafael Fraguas, ‘the climax of his art’,¹⁰⁹ in which, in the words of the *Cervantes Encyclopedia*, he ‘achieved a harmony between illustration and written text that has seldom been matched, perhaps never’ in any edition of Cervantes’ novel.¹¹⁰ The American artist and former Slade professor, Joseph Pennell, praising both Vierge’s consummate skill and originality, wrote that, ‘in the few short years of his working life’, he ‘proved himself one of the greatest illustrators who ever lived’.¹¹¹

Katherine Sherwood, a contemporary American artist, had a left hemisphere stroke in 1997, when she was 44. Her pre-stroke art was somewhat conceptual, even ideological, but her subsequent work, described as raw, intuitive and flowing, feels to her different. She says there is ‘a new ease in my process. I did not feel I had to intellectualize away my every move and an extreme amount of struggle faded away. A freer, more enjoyable state of painting existed far different than in my previous work.’¹¹² David Ross, the director of the San Francisco Museum of Modern Art and former curator of the Whitney, says of her post-stroke work: ‘There

is something more visceral, less intellectual, about these pictures. Her painting now is much better, much more interesting, than before. That's quite miraculous, but it's true.'¹¹³

In 1951, a Bulgarian painter, Zlatyu Boiyadjiev, suffered a severe left hemisphere stroke that robbed him of speech and paralysed the right side of his body.¹¹⁴ He retrained himself to paint with his left hand in an entirely new style, with elements of naivety, but greater vitality. While these matters are inherently subjective, it has been said of the impact of his stroke that 'all his mature and more famous works came thereafter',¹¹⁵ that 'although his style was entirely new, it was in no way inferior to his pre-stroke style: contemporaries spoke of the birth of a new painter';¹¹⁶ and that 'most of his more highly regarded paintings were executed with his left hand'.¹¹⁷ In 1961 a solo exhibition was a *succès fou*. The young critic Atanas Patsev, a member of the new generation of artists himself, reviewed it with enthusiasm: 'From the canvases there flows tension, love, power, in all the colours of the rainbow. This exhibition is not an ordinary event in our artistic life. This is an epic of human will, imagination, art.' An exhibition of his paintings in 1968 was so 'astonishing and breathtaking' that he was nicknamed 'golden Zlatyu' (*zlatyen Zlatyu*, a pun on his name).¹¹⁸ He went on to win the National Prize for painting, the Vladimir Dimitrov Award.

An Italian painter Afro Basaldella suffered a left hemisphere stroke in 1971. By 1973 'he resumed painting at a rate comparable to his premorbid years'. However,

Afro developed a very personal compensation strategy: he would hold the brush with his right hand but kept it up and guided it with his left hand. This determined his choice of style with a strong preference for vertical and horizontal lines which would define an area with clear margins and which would then get filled with colours. Art critics interpreted this as a 'return to Neo cubism', but in reality, his artistic production was markedly affected and conditioned by the severe movement limitation of his right hand and right arm. Afro continued using this technique up to the time of his death in 1976.¹¹⁹

Another minor Italian painter, Gianfranco Fasce, had a left hemisphere stroke which impaired his capacity to convey depth, and initially affected his choice of colour, which he later recovered. 'Despite a severe expressive aphasia, he was able to create paintings that are artistically valuable even though they show a marked change compared to his previous works.'¹²⁰

A prominent Polish painter, known only as 'RL', had a left hemisphere stroke at the age of 51, which left him with loss of speech and right-sided weakness. While previously he had preferred abstract art, which frequently included verbal material in the form of letters, names or numbers that he integrated into his paintings, his work changed. Two self-portraits done, with his affected right hand, five months after his stroke reveal remarkable skill. Over the first year, he continued to paint portraits and landscapes and only started to paint more symbolically again after the first year.¹²¹

Fig. 21. Change of style in artist 'RL' following left hemisphere stroke. Top row: pre-stroke paintings. Bottom row: self-portraits five months after left hemisphere stroke (from Blanke 2007)

Carl Fredrik Reuterswärd, a Swedish painter and sculptor, had a left hemisphere stroke at 55, but a year later he had resumed intensive artistic activity using his left hand. 'The pictorial works were reviewed by several renowned art specialists: changes of style and even of content were judged without loss of artistic quality. The result was described as a gain in emotional and artistic intensity.' The case is reported by Françoise Colombo & Gil Assal who comment that

although both cerebral hemispheres are important for graphic competence, the right hemisphere plays a dominant role for this

ability ... [aphasics] are able to continue their career with remarkable creativity in spite of aphasia and with the other hand. In all observations of left-hemisphere-damaged aphasic artists a change of style is described as having above all an increase in emotional intensity, which in the case of [Reuterswärd] was confirmed by several renowned art critics. ¹²²

Jean-Marie Annoni and colleagues report two ‘professional’ painters whose creativity was altered by left hemisphere strokes, one in a predictable fashion, the other less so. ¹²³ They both continued to paint, but in styles that in each case differed from their pre-stroke idiom. One (ambidextrous) patient migrated, predictably, from a ‘figurative’ style to a more ‘realistic’ one:

He reported that he was ‘more sensitive to the hidden beauty of nature’ and that he ‘wanted to live and paint spontaneously, explore the world, and represent it in its raw strength’. He also indicated a loss of interest in ‘impressionists’, whom he had preferred for the previous 21 years. Impressionism was now no longer sufficiently real or representative of his creative strength. Intriguingly, he said that it was the use of the left hand that led him into this new artistic dimension ... He realised that his creativity was increased by the use of his left hand.

In the other patient, however, although details were ‘simplified’, as one might expect with a left hemisphere stroke, his style became more abstract and symbolic. ¹²⁴

An improvement in technique was noticed in another painter as dementia progressed, a development which, according to the authors of the study could be related to ‘sparing and disinhibition of the right posterior neocortex’. ¹²⁵ Creativity resulting from disinhibition of the right hemisphere by suppression of the left is proposed by Kenneth Heilman, an authority in the field, in a recent review. ¹²⁶ Another survey by the neurologist Geoffrey Schott concluded that, in at least some cases, compensatory changes particularly in the right posterior hemisphere were ‘likely to be pivotal in enabling unusual artistry to emerge’. ¹²⁷

Then there are reports of sudden acquisition of artistic skill following a left hemisphere, but not a right hemisphere, stroke in people who were not artists prior to the stroke. It is hard, however, to know if they had some latent, or unpractised, skill. Was the artistic ‘release’ really arising *de novo*? And, if not, what does any alteration in style tell us? A subject with left prefrontal stroke showed sudden enhancement of artistic skills in realistic painting after the onset of brain damage. Although neuropsychological tests revealed impaired executive function, he performed better than age-matched healthy controls, and the results were paralleled by increased perfusion in the right parietal cortex, including the precuneus and intraparietal sulcus.¹²⁸ Jon Sarkin, a previously rather reserved chiropractor, was seized after a left brain haemorrhage by an insatiable desire to paint, on any surfaces that presented themselves, a desire which took over his life. He said he saw things differently and more vividly than he had before.¹²⁹ In a study of a subject with epilepsy, who became creative after left hemisphere seizures, the authors suggest that artistic tendencies were released by left frontal dysfunction, leading to right hemisphere dominance.¹³⁰ Anne Adams, a cell biologist, is said to have had a passing interest in drawing when she was younger, but never pursued it. As she developed primary progressive aphasia, a degenerative disease affecting the language centres of the left hemisphere, she gave up her scientific career and began to paint prolifically. According to a neuropsychological study, she made ‘striking gains of function’: brain scans revealed increases in both grey matter volume and vascular perfusion in right posterior cortical areas known to be involved in integrating sensory and other information across different modalities. The authors suggest that damage to the left inferior frontal cortex can lead to structural and functional enhancements in the right posterior cortex, giving rise to some forms of visual creativity.¹³¹ The quality of neuroanatomist Jill Bolte Taylor’s stained glass work, painting and sculpture increased following her left hemisphere stroke.¹³² A 46 year-old truck driver with no previous interest in art started to paint prolifically after a head injury that caused extensive left frontotemporal damage.¹³³ His style evolved through four phases of increasing sophistication.

Mazzucchi *et al* conclude their review of painters following stroke:

Painters with right-hemisphere lesions tend to show a much greater deterioration [than those with left hemisphere lesions]. They also may become unable to represent tri-dimensionality, tend to show greater loss of depth and distance, and also an impoverishment in the use of colours. Their main problem, however, is visuo-spatial in nature, leading to [neglect of] the left side of the canvas or imbalances between left and right side of the canvas. There is also evidence of constructional apraxia. How can our data be interpreted in view of our current knowledge of hemispheric specialization as gathered from split-brain patients? They certainly do not lend support to a narrow or exclusive link between art and the right hemisphere, as sometimes expressed in the popular media ...¹³⁴

Well, maybe not as expressed in the popular media. But why fight shy of the obvious? As she says, ‘our data lend support to the view that the left hemisphere tends to apply piecemeal, analytic, and logical computational approaches to the creative process. The right hemisphere mainly has a global holistic approach and has a high degree of specialisation for visuo-spatial abilities.’ Given the weakness of applying piecemeal, analytic, and logical computational approaches to the creative process (see below), the necessity of a global approach, and, in the visual arts at least, of the right hemisphere’s ‘high degree of specialisation for visuo-spatial abilities’, why not just say it? I suspect because of the fear of being taken for one of those simpletons who believe hemisphere differences are of crucial importance.

Dahlia Zaidel has crusaded against the idea that creativity is in any way hemisphere-dependent, and she is absolutely right to warn against jumping to conclusions on the basis of hemisphere damage in visual artists alone, for the reasons I have outlined. She writes of a too early – I agree – adoption of the idea that the right hemisphere ‘specializes in producing and aesthetically reacting to art.’ But it might be somewhat premature, too, to dismiss the possibility. ‘Unfortunately’, she continues, ‘the assumption became prevalent, and eventually was challenged. Indeed, close examination of the artworks of artists with brain injury revealed otherwise.’¹³⁵

In support of this claim she names six sources. Two are her own previous assertions on the subject, which do not take the argument much further.¹³⁶ Two show the remarkable preservation of quality in artists’ work

following *left* hemisphere stroke, which is interesting, but not to her point.¹³⁷ A further paper shows that, after right hemisphere stroke, artists' outputs were altered, but leaves the question of creativity untouched, since it is mainly interested in neuropsychological changes in the visuo-spatial system;¹³⁸ and the last is the paper by Bänzner & Hennerici, which I have already quoted, showing the damaging impact of right hemisphere stroke.¹³⁹

Somewhat briskly, given the problems we both see here, Zaidel writes, 'The current view is that both hemispheres are involved in the creative process and that there is no hemispheric specialisation for creativity *per se*'.¹⁴⁰ But it is not that easy to settle the matter. Both hemispheres are to some degree, in some fashion, involved in everything, as I have repeatedly stated. But that doesn't address the issue of specialisation. She cites two literature reviews in support of her statement, those by Lindell and Mihov. But these are not references that will help her case. Lindell, as we shall soon see, while suggesting that both hemispheres are involved in creativity, concludes that taken as a whole EEG research 'indicates a marked increase in right hemisphere activation during creative tasks ... The research reviewed here suggests that the right hemisphere does play a greater role in creative processing than the left ... there is no question that the right hemisphere plays a critical role in creativity.'¹⁴¹ And we have already seen that Mihov, who also reviews the research to date is hardly a good choice of ally, observing, as he does, that 'researchers of the lateral dominance have, with fair certainty, come to the conclusion that the right hemisphere and its regions are specialized for creative tasking', and that there is 'dominance of the right hemisphere during creative thinking'.¹⁴²

Over this whole area hangs the ambiguity of the word 'specialise'. It's the surgeon and the scrub nurse again. Each works with the other, rarely if ever apart – true enough. And yet one does not normally conclude that the scrub nurse rather than the surgeon actually carried out the operation. It might even be possible, after many years of working together, for them to exchange roles briefly in a crisis, if the surgeon were injured. 'Scan' the theatre to find out who is operating, and you'll come off none the wiser, since there are usually several different actors involved in the key area. Does 'specialise in' mean 'is *exclusively* involved in'? After all, we will never learn anything about hemisphere differences if we wait for a situation in which one hemisphere is 100% responsible for whatever it is, and the

other contributes nothing. It is always a matter of degree – a matter of asymmetry. And when phrases such as ‘marked increase’, ‘greater role’, ‘critical role’, ‘dominance’, ‘with fair certainty ... specialised’, are applied to one hemisphere and not to the other, they convey to me that that required degree, whatever it is, has been reached. But that’s just my judgment.

Relevant here is a paper by Zaidel about the artists Braque and Kokoschka, both of whom sustained head injuries in the First World War. Braque sustained the more serious wound, in the left hemisphere, but after a recovery period, returned to his art, in Zaidel’s words, ‘seemingly unscathed’. In Kokoschka’s case, he is assumed to have had a right hemisphere injury because in the immediate aftermath of the wound he describes his right hand as ‘the one that wasn’t paralysed’.¹⁴³ The site of the bullet wound is not mentioned, and ‘no mention of neuropsychological right hemisphere symptoms appears in the writings about him by others or in his own observations of himself’, as Zaidel says. ‘Whatever the nature of brain tissue damage caused by the bullet, it did not hamper his artistic talent and skills.’

The least one can say is that if nothing here establishes the key role in creativity for the right hemisphere, nothing here rules it out, either, and we’ve got the rest of the chapter to go.

Right hemisphere strokes are much more serious for painters and sculptors, because of the visuo-spatial nature of their work, but it seems not to be simply a matter of the medium. What do we know about left hemisphere stroke in composers?

Composers

There are a number of cases of composers suffering left hemisphere strokes without impairment, and indeed, according to some sources, with renewed creativity, though the assessment is inescapably subjective.¹⁴⁴ Benjamin Britten suffered a left hemisphere stroke in 1973 during a valve replacement operation, affecting the use of his right hand and leading to depression. Yet his creativity was by common consent, unimpaired,¹⁴⁵ and according to one source, the critics are ‘unanimous’ in describing his Third String Quartet, his last major work, written in 1975, two years after the stroke, and completed just before his death, as ‘a masterpiece ... worthy of

comparison with the last string quartets of Beethoven'.¹⁴⁶ My verdict, too. His biographer the composer David Matthews wrote of it that 'the two earlier quartets had been among his finest instrumental works; the Third is their equal in invention, and in range and depth of expression their superior'.¹⁴⁷

Jean Langlais had a burst of creative composition after a left hemisphere stroke in 1984 that had left him initially speechless, and depressed. The works were 'fresh', but 'uneven' in quality.¹⁴⁸ Igor Stravinsky had a left hemisphere stroke in 1956 at the age of 74: he composed more in the following decade than he had in the 1930s and '40s together.¹⁴⁹ His ballet *Agon*, finished the year after his stroke, was his first twelve-tone composition; despite this novelty, it was 'greeted with wild acclaim' on its first night (partly, it has to be admitted, because of the sensational choreography by Balanchine), and is considered one of the greatest successes of his entire career.¹⁵⁰

Vissarion Shebalin had a mild left hemisphere stroke in 1953, and a much more severe one in 1959, neither of which stopped him producing masterpieces: Shostakovich said of his Fifth Symphony, composed in 1965, that it was 'a brilliant creative work ... a creation of a great master'.¹⁵¹ His work remained, like Stravinsky's post-stroke music, innovative and adventurous, and 'with a new richness and depth',¹⁵² with fewer 'inhibitions and influences'.¹⁵³

Alfred Schnittke had his first left hemisphere stroke in 1985, aged 50, and it left him in a coma. He was declared clinically dead on more than one occasion, but recovered and carried on composing with undiminished energy. After this and before his second stroke six years later, in 1991, his output was 'three times greater' than it had been before the stroke. After the second stroke and before his third stroke in 1994 it was 'astounding'. He said it was 'as if I can visualise the final shape of [the] piece while previously I would see something more or less suitable'. He reported a reduction in analytic processing and an increase in intuition: he considered this a positive development for his composition. He referred to his post-stroke period as 'life after death', or a 'second circle of life'.¹⁵⁴

And, perhaps of some interest, both Handel and Bach are thought to have suffered a left hemisphere stroke, after which their composition was in no way inferior, and arguably superior.¹⁵⁵

There are even cases of those who, after a left hemisphere stroke, developed a sudden interest in and understanding of music, again as though something had been released. One subject who was not particularly musical previously became 'hypermusical' following a left hemisphere stroke.¹⁵⁶ In his book *Musicophilia*, Oliver Sacks reports similar cases, all following left, not right, hemisphere damage.¹⁵⁷

'By contrast', according to Yuri Zagvazdin in his apparently exhaustive review of the literature, 'descriptions of cases in which composers had right-hemispheric stroke are difficult to find.'¹⁵⁸ He mentions only two. Engelbert Humperdinck recovered and wrote some music, helped by his son, after a right hemisphere stroke, of what creative status, it is hard to say; another composer, however, 'lost his ability to create music as a result of his right frontoparietal and posterior temporal cerebrovascular lesions'.¹⁵⁹ Two cases overlooked by Zagvazdin involving right hemisphere stroke are known to me from the literature. Tedd Judd reported a composer who was a music teacher: after his right hemisphere stroke, he went back to teaching at around three months, and after a year had resumed conducting an orchestra. However, his musical output remained very limited, despite efforts to continue composition.¹⁶⁰ And Howard Gardner reported the case of a young composer, a lecturer at a conservatory, who after a right hemisphere stroke remained knowledgeable about music and carried on in his teaching post satisfactorily, but lost interest in composing.¹⁶¹

The case of Maurice Ravel is tragic. He had a degenerative brain disease the nature of which is speculative, and which resulted in his losing his speech. It appears to have affected his left hemisphere considerably more than his right. According to neurologist Richard Cytovic this

revealed a right-sided cognitive system that was disconnected from the capacity to 'translate the patterns which were his music into symbols'. He was 'able to "hear the music in his head"' but had 'an inability to "get out" what his right hemisphere had created'. The loss affected him bitterly. He died after an exploratory operation which found no structural abnormality.¹⁶²

These were painters and composers. But what happens to those, such as poets, for whom language is their creative medium?

Poets

The poet William Carlos Williams first suffered a left hemisphere stroke in 1951, at age 68, and then a further subsequent one a year later. The second stroke resulted in paralysis of his right arm, a visual field defect, an expressive speech impairment, and word-finding difficulties. Despite his language problems, for the remaining 11 years until his death he continued to write poetry prolifically. The poems he wrote following the strokes are deemed amongst his finest work. His creativity and skills as a poet were unaltered and he went on to receive the Pulitzer Prize.¹⁶³

Similarly, in 1990, the well-known and highly regarded Swedish poet Tomas Tranströmer lost his speech and the ability to use his right hand after an extensive left hemisphere stroke. In spite of a severe non-fluent dysphasia with dysgraphia (in other words, both speaking and writing became for him difficult and halting), Tranströmer kept producing poetry of the highest calibre. He carried on playing the piano with his left hand and enjoying music. And through music and poetry, he overcame the communication problems imposed by his stroke. He was never a writer of long poems, but following his stroke Tranströmer's style became even more terse and telegraphic, and densely connotative, in a manner reminiscent of the *haiku*.¹⁶⁴ In 2011, 21 years after his stroke, he was awarded the Nobel Prize for literature.

Walt Whitman suffered a series of strokes, some of which affected his left hemisphere and some his right hemisphere: it is therefore virtually impossible to draw any conclusions from his case.

Semantic dementia (also known as semantic variant primary progressive aphasia, or svPPA) is a degenerative condition affecting primarily the language centres of the left temporal lobe. It is known that semantic dementia can lead to *de novo* creativity in the visual arts, and we have seen an example in Anne Adams. However, a study of three subjects who developed semantic dementia claimed that they all had *de novo* creativity in the verbal domain. Actually, only two of these truly had left- greater than right- disease involvement. Nonetheless these were the ones that actually did show new verbal creativity, while the third, in my view, did not. The first subject reported that 'nature inspired her to write beautiful things'. Previously uninterested in writing, at 56 she compiled a large volume of poems. The second subject became more religious and evinced 'a new

fascination with words manifested as pressured speech, rhyming, frequent punning, and interest in word games and puzzles. He created montages with images and his own poems.' The third subject, however, had greater disease involvement in the right hemisphere than the left: she showed no evidence of increased linguistic creativity, or poetic inclinations of any kind, becoming merely 'extremely verbose' and disinhibited. [165](#)

EFFECT OF LESIONS ON CREATIVE PROBLEM-SOLVING

Fortunately we do not have to rely on ‘experiments of nature’, such as stroke or tumour. Using techniques such as TMS, or another safe and painless technique sometimes used in stroke rehabilitation called transcranial direct current stimulation (tDCS), researchers can get relatively ‘clean’ insights into the contributions of different brain regions to aspects of the creative imagination. One study examined visual memory, known to be vital to creativity, in 12 subjects, each in three conditions: (i) the normal state; (ii) with suppression of the right anterior temporal lobe and excitation of the left anterior temporal lobe; and (iii) vice versa. Only those in the third condition, in which the right hemisphere is excited and the left hemisphere suppressed, showed improvements.¹⁶⁶ More intriguingly, by simply suppressing the left frontotemporal region, nearly one-half of subjects can perform new skills, during the stimulation and for a short period after, that they could not perform before, such as, for example, realistic drawing in three dimensions.¹⁶⁷ Other studies have similarly found that just suppressing the left dorsolateral prefrontal cortex increases problem-solving ability,¹⁶⁸ facilitates the making of remote associations,¹⁶⁹ enhances the flexible generation of unusual uses for objects,¹⁷⁰ and enhances visuo-spatial creativity.¹⁷¹ Deactivation of the left and activation of the right prefrontal cortex was associated with increased creativity in all domains studied: conceptual expansion, associative thinking, and set-shifting ability.¹⁷²

It appears that calendrical calculating autistic savants engage the posterior right hemisphere to solve seemingly impossible maths problems.¹⁷³ Donald Treffert, who has spent his life studying savants, had by 2010 assembled a worldwide registry of 319, of whom 32 had the acquired form. In a paper in *Scientific American*, he reports that in most of these acquired cases, leading to exceptional mathematical, musical or artistic talents, there was damage to the left hemisphere, leading to a release phenomenon involving recruitment and rewiring in the right hemisphere (he calls this the ‘three Rs’).¹⁷⁴ Savant syndrome is usually associated with a knockout of the left frontotemporal area, whether by birth, or by accident,

or by TMS.¹⁷⁵ And as if to confirm this, a mathematical prodigy was found to be activating mainly right hemisphere prefrontal and temporal areas:

calculation expertise was not due to increased activity of processes that exist in non-experts; rather, the expert and the non-experts used different brain areas for calculation. We found that the expert could switch between short-term effort-requiring storage strategies and highly efficient episodic memory encoding and retrieval, a process that was sustained by right prefrontal and medial temporal areas.¹⁷⁶

One of the oddest examples of savantism is that of a nine year-old Mexican boy who in a robbery sustained a bullet wound to the left hemisphere so severe that for two years he was mute, deaf, and paralysed on the right side. When he regained speech, he had ‘completely shed the dialect of the region of his birth’. Despite studying hours a day, he was unable to learn more than a few phrases in English, read, write without a model, or do arithmetic. However, he acquired sudden mechanical skill and was able to dismantle, reassemble and modify multigear bicycles, as well as inventing a punch bag that could simulate the bobbing and weaving of a live opponent. Although he had never received any artistic instruction, he was able to copy pictures accurately. ‘One of the most amazing things that he does is a series of tricks with strings and small objects’, we are told. He demonstrates these tricks to others, but no-one else has been able to do them.¹⁷⁷

Convergent thinking is intensified if the left prefrontal cortex is stimulated,¹⁷⁸ and conversely divergent thinking is enhanced by right frontal stimulation.¹⁷⁹ Creative problem-solving is of particular interest because measurement is relatively objective compared with artistic skill. Solving the nine-dot problem is an example. The puzzle presents a regular grid of nine dots: the challenge is to link all nine dots using four straight lines or fewer, without lifting the pen and without tracing the same line more than once.

Fig. 22. The nine dot problem

The solution requires a typically right hemisphere insight, since it demands ‘thinking outside the box’. The classic solution is shown later in this chapter.

The majority of studies over the last century found that no participant who has not previously encountered the problem can find a solution within the time span of the test. However, using tDCS, which delivers a constant, low-level current using electrodes placed on the scalp, after 10 minutes of excitation to the right anterior temporal lobe and simultaneous suppression of the left, more than 40% of participants did so. Not one subject did so during sham stimulation.¹⁸⁰

For a long time it has been known that, as mentioned earlier, it is possible to cause temporary excitement of one hemisphere at a time by irrigating the contralateral external auditory canal (ie, the ear canal on the other side) with cold water.¹⁸¹ A more recent development called galvanic vestibular stimulation achieves similar effects using electrical current. Stimulating the right hemisphere in this fashion increased originality, while stimulating the left hemisphere decreased it.¹⁸²

In some degenerative neurological conditions such as Parkinson’s disease, a technique involving the implantation of electrodes in the brain (deep brain stimulation, or DBS) has met with considerable success in treating symptoms. As an associated finding, when the left hemisphere is stimulated, both artistic creativity and appreciation are reduced. When the left hemisphere DBS is switched off, patients’ creativity and artistic appreciation scores are relatively enhanced.¹⁸³ The researchers suggest that

left hemisphere activation results in right hemispheric suppression, thus decreasing artistic creativity.^{[184](#)}

Fig. 23. The nine dot problem: solution

EVIDENCE FROM HEALTHY ARTISTS AND COMPOSERS

Studies have been carried out more directly on healthy artists and composers. Artists exhibited ‘strong right hemispheric dominance’, which was much weaker in non-artists; and this was present not only when they were engaged in a creative task, but when they were directly perceiving or visualising works of art – and indeed when at rest.¹⁸⁵ Another recent study found that in a group of experienced artists, activity in the right prefrontal cortex was high but activity in the left prefrontal cortex, and bilateral posterior cortex, suppressed. According to the authors of the paper, this was in keeping with previous studies of artistic creativity, which ‘all point to right hemispheric dominance, particularly of the frontal area’.¹⁸⁶ Composers activate ‘areas specific to melody generation’ in the right temporal pole and right frontal operculum.¹⁸⁷ In both male and female composers, the compositions that received the highest ratings were by subjects that had smaller left hemisphere advantages in verbal processing, suggesting a greater reliance on the right hemisphere.¹⁸⁸ And while an fMRI study suggested that activity in both the left anterior dorsomedial prefrontal cortex and the right anterior middle temporal gyrus was directly proportional to the creative quality of metaphors, the great preponderance of evidence, which I have reviewed earlier, suggests that of the two, the right middle temporal gyrus is the more significant, despite the verbal nature of the task.¹⁸⁹

It seems that creative individuals do have different patterns of brain activity, even when not actively engaged in a creative task. According to one study,

insightful individuals show greater right hemisphere activity at rest, relative to analytic individuals ... The fact that an insight-related hemispheric difference can be found in the resting state suggests that the functional hemispheric asymmetry occurring during problem solution may have its origin in structural hemispheric differences.¹⁹⁰

Such differences include the cytoarchitectonic differences described earlier in this chapter.

Insightful individuals also show larger and more diffuse activation of the visual cortex compared to analytical individuals, even when the resting-state EEG is performed with the eyes closed.¹⁹¹ If it is true, and it seems to be, that work is constantly ‘incubating’ in highly creative minds, particularly analogical, visual or *Gestalt* thinking, this would make sense, since they are not creating only when overtly engaged in a task.

Such individuals may generally have more diffuse and outwardly directed attention, write John Kounios and Mark Beeman, two of the best known names in creativity research,

but successful insight solving involves transiently redirecting attention inwardly during the preparation for and solving of a problem. It therefore appears that the tendency to solve problems insightfully is associated with *broad perceptual intake* as the default mode of resting-state attention deployment, coupled with the tendency to focus *inwardly* in preparation for, and during, solving. In contrast, analytical people’s resting-state attention is less outwardly focused during the resting state and less inwardly directed during preparation and solving.¹⁹²

The capacity for both ‘broad perceptual intake’ and outwardly directed attention is greater in the right hemisphere; and so it is for internal visualisation, as we shall see.

CREATIVE THINKING STYLES

There is, then, a considerable body of evidence from naturally occurring, or temporarily experimentally induced, lesion studies, from direct observation of creative artists, and from a host of different kinds of experimental studies, that quite consistently suggests not just that depressing the right hemisphere tends to depress creativity, including originality, flexibility and divergent thinking, but that depressing the left hemisphere enhances creativity, probably because the mind is released from tendencies towards the linear, explicit and linguistic modes of apprehension typical of the left. There is in fact direct evidence that both rationalising and verbalising have a damaging effect on creativity, at least during the generative process itself. The evidence on this matter is detailed in Chapters 17 & 18. However, an fMRI study at Stanford is particularly interesting. Not only did it find a negative correlation between creativity and involvement of the left prefrontal cortex, it also found that greater involvement of the cerebellum improved creative problem-solving.¹⁹³ Since the cerebellum is entirely unconscious, and involved in sensorimotor co-ordination, this confirms both that the unconscious mind and the body play an important role in creativity, and that thinking is not separate from perceiving, feeling and bodily motion (a topic I will return to when I discuss the cerebellum in Chapter 23).

In many situations, the effort to reduce mistakes may potentially interfere with the achievement of insight by limiting time and resources and by directing attention toward precision, and away from reflection. The effort at reducing mistakes – the documentation of sources and of areas of uncertainty, and the assignment of probabilities to assumptions – can get in the way of apprehending new patterns.¹⁹⁴ Chrysikou and colleagues write that:

An extended body of research supports the notion that a particular region of the PFC, the left ventrolateral prefrontal cortex, is implicated in tasks that ... are guided by a set of explicit rules and ... require one correct response, the form of which is typically known to the participants.¹⁹⁵

It's also not just a matter of the convergent approach being uncreative, but of its positively leading to a certain kind of mistake. Insight can be mistaken, but so can analysis.¹⁹⁶ Subjects who solve predominantly by insight tend to make errors of omission ('time-outs') rather than errors of commission (incorrect answers); those who solve analytically make the reverse pattern, giving incorrect answers, rather than failing to complete. When confronted with a deadline, insight solvers will simply not complete the task if the answer has not come in time. However, when analytic solvers run out of time, they tend to guess, often incorrectly, before the deadline, offering the hypothesis they were busy evaluating at the time.¹⁹⁷ Don't forget that, to put it bluntly, the left hemisphere is overconfident and is prone to bullshit.

Creative intuitions frequently begin with *not* knowing, with the recognition that the obvious does not apply, that something here does not fit. If you are engaged in narrowing down to the most likely, are less inclined to doubt what you believe you know, and are inclined to preserve the current paradigm at all costs, rather than take seriously a finding that requires its modification, it is clear that you will be less likely to find something new – or accept it when it is pointed out to you.

EEG studies of creativity

EEG studies are another source of information on creativity, but, like imaging studies, they suffer to some degree from problems of interpretation if taken on their own. Nonetheless, a number of EEG studies suggest greater right hemisphere activation in both divergent thinking tasks and in insight tasks, very few suggesting the opposite.¹⁹⁸ A sentence generation task, starting from just four letters, produced significant activity in both frontal lobes, but additionally in the right, but not left, parietotemporal region (note that this is a language-based task, which necessarily involves the left hemisphere).¹⁹⁹ In two types of divergent thinking tasks, the posterior regions of the right hemisphere displayed higher involvement than the left in both conditions.²⁰⁰ One study found (although the results were far from straightforward) a relationship between the right hemisphere and both intelligence and creativity that has been found elsewhere: 'high IQ individuals showed more co-operation between brain regions in the right

hemisphere during divergent thinking tasks.’²⁰¹ In another study, in successful cases of insight ‘gamma band power was increased in right fronto-central and frontal electrode.’²⁰² Annukka Lindell, in a recent systematic literature review, concludes that taken as a whole EEG research ‘indicates a marked increase in right hemisphere activation during creative tasks’. ²⁰³

Neuroimaging studies of creativity

With all of this in mind, let’s look at the imaging literature briefly. A recent study claims to offer ‘unprecedented empirical support for a crucial and specific contribution of the right hemisphere to creativity’.²⁰⁴ Several imaging studies suggest that the right prefrontal cortex has a special role to play in ‘open-ended’ inference tasks with no right or wrong answers.²⁰⁵ A study of divergent thinking found that the right, but not left, dorsolateral prefrontal cortex was activated, consistent, as the authors remark, ‘with a number of earlier studies which also found predominantly right-sided activity during divergent tasks’.²⁰⁶ A study of the neural correlates of creative writing as compared with copying showed that ‘all regions showed lateralized activity to the right hemisphere’, with the strongest activation in the right medial temporal pole. ²⁰⁷ A study comparing an artist with a non-artist drawing a portrait found that while both showed an increase in activity in the right posterior cortex, a region normally associated with facial perception and processing, ‘the skilled artist showed greater activation in the right frontal area’.²⁰⁸ In a design task, the creativity of experts was proportional to the degree of dominance of the right prefrontal cortex over the left. The results suggested that there was a direct, suppressive, effect on the left parietal cortex, while the activity of the right prefrontal cortex was facilitated. In expert artists only the right prefrontal cortex and right parietal cortex were activated, whereas in the novice group the activations were bilateral: it was suggested by the authors that in artists a transcallosal pathway was exerting inhibitory control of the right on the left prefrontal cortex.²⁰⁹

TOGETHER OR APART?

That raises the interesting question, whether it is co-operation, or independence, of the hemispheres that leads to creative excellence. In her review, Lindell emphasised that the whole brain is involved in everything (granted):

Although the research reviewed indicates greater right hemisphere activity during creative tasks, the interaction between many varied, often distant, cortical regions across both the left and right hemispheres is also a crucial component of creativity. This interaction facilitates the integration of a variety of separate cognitive abilities, fostering creative thinking ... Interhemispheric interaction would clearly be valuable here as the integration of information from both the left and right hemispheres via interhemispheric interaction can bring together more distantly related semantic concepts than if a memory search were theoretically restricted solely to one region or one hemisphere.

On the face of it this assumption – which is all that it is – seems reasonable. Why would a process that depends on bringing things together not produce best results when both halves of the brain are integrated?

But what if you were not trying to integrate two elements, each of them itself integrative, but trying to integrate an integrative element with an analytic one? It has been claimed that interactions between visuo-spatial and analytic thinking, and between conscious and unconscious thought processes, are necessary for creativity.²¹⁰ But this is a half-truth. At the generative stage, it is important that they are kept apart; all the evidence is that premature involvement of conscious, analytic thinking stops creativity in its tracks. At some stage the results of the generative process can be subjected to linguistic formulation, conscious inspection and analysis, *provided* those factors have been kept at bay until creative generation is far advanced.

This is important because it underlies the impression that Lindell gives – and others give – of doing the mental splits. On the one hand, they see

clearly that the right hemisphere is the key factor; yet, on the other, common sense (and an instinct for self-preservation) seems to tell them that things ‘must’ be better if both hemispheres are involved. Thus she says: ‘The research reviewed here suggests that the right hemisphere does play a greater role in creative processing than the left ... there is no question that the right hemisphere plays a critical role in creativity’; but she concludes, on less evidence, that the left hemisphere is also ‘vital’.

However, we have already seen that the right hemisphere performs much better when not open to interference from the left hemisphere. Several studies have separately found that there is more ‘decoupling’ and independence of the hemispheres in creative individuals.²¹¹ In a study of corpus callosum size in relation to creativity, there was found to be an *inverse* association, ie, smaller callosal size was associated with higher creativity.²¹² This may be because decreased interconnectivity enhances hemisphere specialisation, which in turn benefits the incubation of ideas that are critical for flexibility, divergent thinking, and originality.²¹³ There needs, however, to be some connectivity, even if only to allow a degree of inhibition, and a degree of access to the left hemisphere’s language repertoire: total callosal agenesis (failure to develop) appears to diminish creativity.²¹⁴ There will be a need for both inhibitory and facilitatory connexion at different points in the process.²¹⁵

One rather nice detail suggests that relative hemispheric independence may be a part of genius, at least in some cases: one of CS Peirce’s accomplishments was that he could write down a question which was bothering him with one hand, and with the other simultaneously write the answer.²¹⁶ Perhaps Leonardo’s brain was similarly flexible: he could write, mirror fashion, with either hand, or both at once.²¹⁷

In summary, to quote Waismann, there is something

so wrong with the whole way in which such discoveries [scientific, philosophical or artistic] are so often presented – as if they were the result of a ‘method’ or ‘procedure’, as if the great men arrived at their solutions by drawing logical inferences. This leaves out the most essential thing– the flashing of a new aspect which is *non*-inferential. The moments of seeing cannot be foreseen, any more

than they can be planned, forced, controlled, or summoned by will-power.^{[218](#)}

THE GENTLE ART OF DEBUNKING

This review of evidence may seem to have been somewhat repetitive. That is because I need to establish just how extensive and multifaceted the evidence for right hemisphere superiority in creativity is. And here's why. Despite this extremely substantial body of findings of many different kinds gathered over many years, it has been suggested, rather in the face of reason as well as of the evidence, that critical and convergent thinking, eliminating error and aiming for the one correct answer, might be creative; and this goes with a denial that the right hemisphere plays the predominant role, or even an important role at all, in creativity. The assertion is usually made in passing, almost a ritual utterance that absolves the faithful scientist from being tainted with the mortal sin of taking hemisphere differences too seriously. But there is one influential and insistent such voice, that of Arne Dietrich at the American University of Beirut, who has taken the trouble to marshal an argument in detail in a well-known scholarly paper, followed up by a full length book, 'debunking', as he jauntily puts it, a range of 'myths' about creativity, the most prominent being that of the special role of the right hemisphere. I am therefore obliged to take a closer look at the evidence he cites, to see if he is right about this.

The paper was written in conjunction with a colleague, Riam Kanso.²¹⁹ In it the authors review 63 papers on divergent thinking, creativity and insight. They begin by casting doubt on the whole idea that divergent thinking is of particular relevance to creativity. As I have already suggested, I agree that studies of divergent thinking – how many uses can you think of for a tin can? what's the word that links BREAD, GRAPE and CAKE?²²⁰ – are a poor substitute for what's done by Shakespeare or Mozart. But to the extent that being creative means having the originality to see something new, it can't be done by convergent thinking in itself (though that may play a subsequent, auxiliary, role). You can't be creative by just following the usual rules.

Not so according to Dietrich & Kanso. 'It is obvious at a moment's reflection – and certainly was to Guilford himself', they write:

– that creativity can just as well be the result of a convergent process. What would we otherwise make of Edison’s assembly line, nearly algorithmic approach to inventing; Bach’s methodical way of composing hundreds of cantatas; the imaginative ways in which National Aeronautics and Space Administration engineers solved the problems of the otherwise doomed Apollo 11 mission; or the countless creative solutions generated by systematically eliminating alternative possibilities?

In another paper Dietrich goes further: ‘Once we understand that creative acts arise from both divergent and convergent processes, the distinction becomes meaningless as the theoretical basis for the study of creativity.’ ²²¹ Really, meaningless? I’m in favour of more, rather than fewer, distinctions myself, when it comes to understanding creativity, and it seems a bit incautious to sweep such a basic one out of the way. It doesn’t particularly matter what Guilford thought. However, since the matter is raised, Guilford saw, yes, that we need both divergent and convergent thinking; but he thought, as most people do, that convergent thinking had its place at a later stage, after divergent thinking had played its part (and that our educational system was wrong to encourage convergent thinking at the expense of divergent thinking).

Dietrich & Kanso also confuse problem-solving with creativity. Not all problem-solving is creative. Marshalling and analysing data for your tax return requires convergent thinking to solve the problems set by the Revenue Service’s demands, but, outside of criminal circles, it is not widely held to be a creative activity. However, establishing the existence of Fuchsian functions required jettisoning convergent thinking – here is Henri Poincaré’s famous description:

For fifteen days I strove to prove that there could not be any functions like those I have since called Fuchsian functions. I was then very ignorant; every day I seated myself at my work table, stayed an hour or two, tried a great number of combinations and reached no results. One evening, contrary to my custom, I drank black coffee and could not sleep. Ideas rose in crowds; I felt them collide until pairs interlocked, so to speak, making a stable combination. By the next morning I had established the existence of

a class of Fuchsian functions, those which come from the hypergeometric series; I had only to write out the results, which took but a few hours.

However, once their existence has been established, working with Fuchsian functions *does*, right enough, involve, for you and me, convergent thinking. But not until the discovery – the creative element – is made. Inventing the bagless vacuum cleaner involved James Dyson in making a connexion between an air-filtering system used in sawmills and oil refineries, called an industrial cyclonic separator, and a domestic floor cleaner: divergent thinking. It then took him and his team 15 years and 5,127 attempts, once the insight had been had, to build it: mainly convergent thinking.²²²

And what of Edison, Bach and Apollo 11? Of course, inventions don't come without application of effort, and are often tweaked or incrementally improved, but it would be silly to suppose that they are merely the product of following rules, systems or procedures. 'The creative mind is a mind that looks for unexpected likenesses', wrote Jacob Bronowski. 'This is not a mechanical procedure, and I believe that it engages the whole personality in science as in the arts.'²²³ Nor is mathematics a matter of following procedures. 'Math is not about following directions, it's about making new directions,' writes mathematician Paul Lockhart:²²⁴

To do mathematics is to engage in an act of discovery and conjecture, intuition and inspiration; to be in a state of confusion – not because it makes no sense to you, but because you *gave* it sense, and you still don't understand what your creature is up to; to have a break-through idea; to be frustrated as an artist; to be awed and overwhelmed by an almost painful beauty; to be *alive*, damn it.'²²⁵

Edison was right that hard work counts and he was relentless in experimentation, but his experimentation was guided by insight. Edison is one of the few people to have had a light bulb moment about light bulbs, but he did have one. 'Of course Edison's most famous invention was the light bulb', writes Wouter Boon, author of *Defining Creativity: The Art and Science of Great Ideas*:

Though electric lights had already been invented to light the streets, Edison introduced it into people's homes. To do so he needed to bring together a wide range of knowledge about the light bulb itself, the fixtures, the electricity generators and the circuits getting the electricity from the power station to the homes. It was like a big puzzle, he had to combine all the pieces into one invention. *Making unfamiliar combinations of familiar ideas; that is what creativity is in a nutshell* ... The idea of using bamboo as the light bulb filament came from Edison's memory ... Making associations with our memory is very important for being creative, since it allows us to use 'old' ideas in new combinations ... Edison didn't attend public school for very long. One of the reasons was that his mind often wandered. This made him unfit for the traditional schooling system. Edison did take naps. Whenever and wherever he needed them – even on his workbench. This wasn't the only way he recharged his batteries. The laboratory had a pipe organ at the back and often around midnight Edison himself would play it and everyone would sing along and have a drink. Generally, it is important for creative minds to find relaxation. This not just suits the purpose of recharging the batteries, but it is also important for incubation, the phase in the creative process during which the acquired knowledge gets a chance to sink in, be reorganized and combined with other (seemingly irrelevant) ideas by the unconscious brain.²²⁶

Or Bach. Was his really just a methodically 'convergent' mind, finding the one, clearly right, solution by following the established procedures – what Dietrich elsewhere refers to as Bach's 'assembly line tactic'?²²⁷ To anyone who knows the first thing about Bach, this is a very odd idea indeed. He wrote regularly, as did Shakespeare and Mozart, but this does not mean that he, or any of them, followed an 'assembly line tactic'. We don't need to rely only on our own twenty-first-century judgment – after all we might be committing the unforgiveable sin of 'romanticising' – we can turn to what his contemporaries thought. Johann Birnbaum, a professor in rhetoric at Leipzig who died two years before Bach, praised 'the astonishing mass of unusual and well-developed ideas' in Bach's music. 'This does not refer', according to Christoph Wolff, the eminent musicologist and Bach's biographer, 'to traditional invention, guided by an

art of devising melodies and themes, one governed by musical rhetorical models.’²²⁸ Bach’s obituary speaks of ‘strange ideas’, and describes his melodies as ‘uncommon’, ‘always divergent’ (two centuries before Guilford!), and ‘fanciful ... unlike that of any other composer’.²²⁹ Speaking in 1784 or 1785, the composer Christian Schubart wrote that ‘there is no mistaking the originality of Bach’s genius ...’²³⁰ So great was his genius that even composing to a schedule did not blunt it.

The myth that the idea of the creative genius has been debunked is well overdue a bit of debunking of its own. David Cope developed a way of analysing enormous numbers of Bach fugues so as to gather some generative forms that his machine EMI (Experiments in Musical Intelligence) could then use, *retrospectively*, to copy Bach. But, as we have seen, Bach’s genius was not itself a copy. And Bach’s feeling, his spirit, the human meaning of his music matter more than any structural elements taken out of that context: again a machine could only achieve a simulacrum of something that would, had it come from a human, convey feeling, and then as an incidental occurrence in one out of many, many attempts. That, however, was not Bach’s method. Already by the age of 19 Bach had composed a piece of music so deep, so moving, that no machine could ever begin to rival it.²³¹ And it was also, already, quite original.

Mozart is often trotted out as one of those who achieved what he did by conscious application unaided by unconscious or divergent thinking, as for example in Robert Weisberg’s deeply flawed book *Creativity: Beyond the Myth of Genius*. Weisberg effectively denies that highly creative people make ‘mental leaps’, asserting instead that their thinking is merely of the plodding sort we all could manage if we just put in enough hours. This is about as wrong as you can get, not just, obviously, in the creative arts, but in maths and science, as we will see in Part II. (It seems to me a natural expression of our curiously resentful age, so suspicious of individual differences, and in which the rhetoric is that we all have it in us to be geniuses: a clearly false assumption, though some people presumably derive comfort from it.) Of course ground work needs to be done – nobody denies that – you need to know your chosen field well, and persistence is often needed to keep going at something till you get the solution. But it would be a mistake to conclude that the creative insights, when they come, are a consequence of following rules. In a letter to a Baron B — who had

enquired about how he set about writing, and how it was that his work was so distinctive, Mozart wrote (the text may have been embellished: see note):

How do I write, and how do I come to flesh out what are large, general ideas? I really can't tell you any more than this – because I myself don't know any more about it, and can't get any further with it.

It's when I'm feeling right and things are good, perhaps riding in a coach or taking a walk after a good meal, or in the night when I can't sleep – these are the best times, when thoughts come flowing into my mind, like a stream. How they come, and where they come from, I don't know, and I can't do anything about it. The ones I like I keep in my head and go around humming them; at least that's what people tell me. If I hang onto them, I soon come to see, one by one, how to use such and such a phrase, how to make a tasty dish out of them all, using counterpoint, and respecting the timbre of the different instruments, etc, etc, etc. That fires up my soul, and as long as I am not distracted, the work grows; I expand it, and it becomes clearer, until I have the thing pretty much finished in my head, even if it's long; so that from then on I see it all in my mind's eye at a glance, much as one sees a beautiful picture or a pretty woman, and I don't hear it sequentially in my imagination, as it will have to be later on, but, as it were, all at once ... When I later come to write it down, I just take, straight out of my brain box, what's already assembled there, as I've explained. For that reason it goes down on paper pretty quickly, since, as I say, it's really already finished, and rarely turns out much different from what was in my head all along. That's why I don't mind being disturbed while writing; and I quite like all sorts of things going on around me; I carry on writing just the same; and can even chat away at the same time about hens and geese, or Jack and Jill, or whatever ... As to how it is that during the process my pieces come to take on a Mozartian form or style, one not like anybody else's, it's like asking why my nose is big and curved – it's Mozartian, and not like other people's! I don't aim for distinctiveness and I can't really describe what's different about my style. But it's obvious that people who really have something particular about them will be different from each other on the inside

as well as on the outside. All I know is that I am not the author of either kind of difference.²³²

Note here that Mozart describes all the elements that are *not* rule-following, assembly line production, and how they all have right hemisphere characteristics: he can neither see into nor control the process; there is a flow or stream (thoughts come ‘*stromweis*’); he cannot say where it comes from; it happens without him needing to write it down, and he sees it as a whole, like a picture, not serially; and it has a unique quality, which is not the result of contrivance, but is as much a part of him as his nose.

And then there is Handel, who wrote the whole of *The Messiah*, approaching four hours’ worth of some of the greatest and most inspired music ever written, in just over three weeks, between 21 August and 14 September 1741, interestingly while still recovering from his left hemisphere stroke. Of those three weeks of inspired creation, during which music seemed to pour out of him, he said: ‘Whether I was in my body or out of my body I know not. God knows it!’²³³ He also said, though, no doubt, this will afford Dietrich and his colleagues no end of merriment: ‘I did think I did see all heaven before me, and the great God himself’.²³⁴

This is not a proto-Romantic phenomenon. There are examples from many periods and cultures.²³⁵ For example, the great Elizabethan composer William Byrd wrote that

In the very sentences (as I have learned from experience) there is such hidden and concealed power that to a man thinking about divine things and turning them over attentively and earnestly in his mind, the most appropriate measures [melodies] come, I know not how, as if by their own free will, and freely offer themselves to his mind.²³⁶

So much for the assembly line theory of musical genius. I could multiply the impression by reference to countless individuals – composers, poets, scientists and mathematicians – on their own creativity. Ghiselin collected together nearly 40 of them, ranging from Wordsworth to Einstein, from Poincaré to Picasso.²³⁷ What he emphasises, and they emphasise, is the necessity of things going on at the crucial stage either wholly outside of

consciousness, or at most on the margins of conscious awareness, *not* in the centre of the attentional field. Ghiselin concluded from his survey that ‘production by a process of purely conscious calculation seems never to occur.’²³⁸ The mathematician Jacques Hadamard surveyed over 100 scientists and mathematicians and drew similar conclusions.²³⁹ Carl von Weizsäcker wrote:

A great scientific discovery is the recognition of a particularly simple and fundamental form which heretofore had been hidden in a chaos of appearances and misunderstood theories. It is often described as an inspiration or special gift of grace which comes to the researcher when and as it pleases, like an answer from “another authority” and then almost without effort on his part. It is never viewed as the inevitable result of his research effort.²⁴⁰

And I don’t know the inside story of Apollo 11, but the most serious of the many technical problems it faced was apparently this. During the landing, the lunar module’s engine thrust started to fluctuate wildly due to a programming error. The algorithm that controlled it had become only marginally stable. Then, according to engineer Bart Hennin:

a second brilliant programmer found an ingenious way to rewrite the software so there was only effectively a 0.02 second delay ... Had the clever 2nd programmer not reduced the delay from 0.03 to 0.02 seconds, the throttle would have gone from meta-stable to COMPLETELY UNSTABLE and the landing(s) would have been impossible! ²⁴¹

If you really think being a ‘brilliant’ programmer is simply following procedures, rather than to a great extent following intuition, talk to a few. This one had minutes to find an ‘ingenious’ solution, which almost certainly means it was not standard, assembly line thinking at all. Dietrich’s own description of the solutions as ‘imaginative’ suggests he knows this perfectly well.

And as to those ‘countless creative solutions generated by systematically eliminating alternative possibilities?’ Isn’t that *precisely*

what the accounts of creative people suggest hardly ever occurs – if at all? Having pointed out that there isn't enough time in the universe for the mind to process all the possibilities, and so it must be selective at a level below consciousness, the great mathematician Henri Poincaré writes:

This, too, is most mysterious. How can we explain the fact that, of the thousand products of our unconscious activity, some are invited to cross the threshold, while others remain outside? Is it mere chance that gives them this privilege? Evidently not. For instance, of all the excitements of our senses, it is only the most intense that retain our attention, unless it has been directed upon them by other causes. More commonly the privileged unconscious phenomena, those that are capable of becoming conscious, are those which, directly or indirectly, most deeply affect our sensibility.²⁴²

In a chapter in Dietrich's new book *How Creativity Happens in the Brain*, modestly entitled 'A disciplined demolition project' – a chirpy overstatement on both counts – he urges that the concept of divergent thinking is incoherent. But, he notes, with just a hint of irritation, 'even when investigators acknowledge the problem in their paper's introductory remarks, mostly because some referee in the peer-review process forced them to, they, undaunted, proceed to use the flawed construct anyway'. How maddening is that? All those psychologists, researching for decades, have been (except, of course, for Dietrich himself) chasing a will o' the wisp. It really is a shame they are so stupid:

... The issue seems simply to be a case of logic 101. If you wish to better circumscribe a phenomenon's existence, you must delineate your proposal from something, a control condition of some kind that either contains its opposite or at least is marked by its absence ... Actually, divergent thinking is only the most influential of a whole stack of such false partitions. Psychologists and neuroscientists, often with more enthusiasm than sense, have put forth a number of such forlorn proposals. Open any source on creativity, academic or otherwise, and you will find an extended list of false category formations that aligns creativity with, say, low arousal, defocussed

attention, flow states, lateral thinking, latent inhibition, remote associations, unconscious thinking, altered states of consciousness, madness, alpha power enhancement and, not forgetting, right brains, to name the popular themes. We can add each and every one of them to the list of demolition targets because common sense alone tells you that the exact opposites are also wellsprings of creative thinking and, to complete the factorial crossover, each and every one of them is associated with non-creative thinking. Such category formations flout basic logic.²⁴³

Well, there's lots of rich stuff here. Complex phenomena are likely to have complex correlates. Worthy, therefore, of something more subtle than 'a demolition job'.

Let's start with divergent thinking. I have no love of the term myself – language is inevitably poor at capturing anything subtle. One reason that psychologists go on using the term might be because it – or something very like it – is indispensable. One can't help agreeing with Dietrich, though, about it being 'a case of logic 101'. Because in logic 201, one would discover that things get a bit more complicated, and one needs a more sophisticated approach than the one being touted here. If it is hard to define something neatly, that doesn't mean it doesn't exist: it often means that the phenomenon is complex, or that, though the term one is applying is a useful placeholder for the phenomenon, the phenomenon itself can't be perfectly circumscribed by it. Thus there exist organisms such that we can't say definitively whether they are plants or animals, but I suspect most of us find the distinction useful, and can tell the difference between an elephant and a gumtree.

He complains that there are examples of divergent thinking that aren't creative, and of creative thinking that aren't divergent. The first might be true – though, as I have suggested, what is meant by divergent thinking isn't just a random splurge of ideas, but a process guided by intuition towards its goal. But I doubt there are good examples of creativity that don't involve divergent thinking, at least at key stages. Be that as it may, as a type of argument it is not terribly impressive. I say the warm climate of Southern California is due to its getting a lot of sunshine. You say that my concept of sunshine is incoherent, and that the argument 'flouts basic logic', because sometimes the sun shines and it's not hot, and sometimes it's hot when the

sun doesn't shine. I remain unpersuaded by your view that 'common sense alone tells you' that moonshine is just as good a candidate.

Most matters to do with the human psyche are like this. Take something as real and as devastatingly important as depression. It is best characterised by a constellation of symptoms: low mood, early morning waking, loss of appetite, anhedonia (loss of the capacity for pleasure), loss of motivation, poor concentration, and thoughts of worthlessness, sometimes of suicide. If you want to investigate depression, these are, without a shadow of doubt, what you need to be investigating. It's no good telling me that for each or any of these symptoms, you can show me someone who has it but is not depressed, nor – 'to complete the factorial crossover' – that you can find cases where people who are clearly depressed do not have it – even low mood.²⁴⁴ Both situations are common. Diagnosis by numbers stands to an experienced physician's judgment as painting by numbers does to a Holbein. This is something doctors frequently have to explain to fledgling lawyers, rarely to experienced judges. Back to logic 201.

In any case, one is now naturally fired up to know what Dietrich's preferred alternative is going to be. At last it is revealed: apparently something he calls 'ideational combination'.²⁴⁵

Forgive me for being able to contain my excitement. Ideational combination, or the same phenomenon by other more elegant names, has been consistently fingered for two thousand years as an important element in creativity. I earlier quoted Aristotle: 'the greatest thing by far is to be a master of metaphor [a combiner of ideas]. It is the one thing that cannot be learnt from others; it is also a sign of genius, since a good metaphor implies an intuitive perception of the *similarity in dissimilars*'.²⁴⁶ Notice, by the way, that Aristotle thinks, as I do, that combining ideas well cannot be taught, because it is not a matter of applying rules, procedures or principles, but a matter of intuition. And, while I think of it, Aristotle could have helped Dietrich get over his problem with imprecise concepts. 'It is the mark of an educated man', says Aristotle, 'to look for precision in each class of things just so far as the nature of the subject admits'.²⁴⁷ I'd have thought it was clear that the creative imagination was a reasonable candidate for the less precise approach.

Furthermore, ideational combination, or the seeing of analogies, the making of combinations of ideas hitherto thought to be unrelated, is already one important element in what is indicated by 'divergent thinking'. The

term ‘ideational combination’ is fine as far as it goes, but it only goes so far; in that respect it is no different from the (for the most part perfectly sensible) suggestions, which Dietrich economically dismisses *en masse* as ‘forlorn proposals’. None of them is the last word on creativity, of course, but none of them pretends to be; neither is Dietrich’s ‘ideational combination’. And I’m afraid it is no better at passing Dietrich’s own ‘basic logic’ test. There are, fairly obviously, an almost infinite number of ideational combinations that are completely uncreative; and some productions, widely regarded as creative, that are not (without stretching the concept to the point of meaninglessness) ideational combinations, such as Yves Klein’s nearly 200 monochrome blue paintings, the so-called IKB series. That’s where the concept of ‘divergent thinking’ has the upper hand, since that’s one thing – about the only thing – the paintings do display, apart from a very attractive shade of blue.

But how valid is Dietrich & Kanso’s claim specifically that *right hemisphere* theories of creativity are, in so many words, baloney? So far I have dealt only with broad issues flagged up by Dietrich & Kanso’s paper. But they base their conclusion ‘that creativity, or any alleged stage of it, is not particularly associated with the right brain or any part of the right brain’ on a review of a large number of papers. In order to do justice to their work I would have to examine those papers myself. So, as you would expect, I have. Since dealing with it involves a detailed rebuttal that would interrupt the flow of the chapter as a whole, I have placed it in Appendix 1, to which the interested reader is referred. I imagine Dietrich and Kanso will not welcome the conclusion I suspect the reader will draw.

Lastly let us turn to the question of the relationship between mental illness and creativity.

CREATIVITY AND MENTAL ILLNESS

‘Illness, madness and death were the dark angels who watched over my cradle and have accompanied me throughout my life’, wrote Edvard Munch. ‘Without anxiety and illness, I should have been like a ship without a rudder.’²⁴⁸

When it comes to the topic of creativity and mood disorders, or as Dietrich puts it ‘madness’, it seems that despite his antipathy to this idea (among many others), it is a fair bet that there is a good deal in it, as has been surmised for thousands of years. Dryden famously wrote: ‘Great wits are sure to madness near allied, / And thin partitions do their bounds divide.’ But some two thousand years earlier Aristotle asked: ‘Why is it that all men who have become outstanding in philosophy, statesmanship, poetry or the arts are melancholic?’²⁴⁹ It would have been an odd observation to make if such people were no different from any others, especially since Aristotle was an exceptionally good observer of human behaviour. But it is no more than one might expect if creativity is right hemisphere-dependent, since there is a clear connexion between the right hemisphere and melancholy or sadness. Indeed creativity, sadness, non-verbal thinking, empathy, intelligence and a preponderance of right hemisphere activity are all multiply interconnected.

I have given an account elsewhere of the very extensive evidence from a wide range of sources, including a large number of lesion studies, as well as EEG, fMRI and visual field studies, for a connexion between the right frontal pole and sadness or depression, and between the left frontal pole and euphoria or mania, so I will not repeat it here.²⁵⁰ The lifetime risk of major depression is linked to relatively less left frontal activity for both sexes.²⁵¹ And such tendencies affect our everyday experience; to take just one example, those with greater levels of right frontal activity rate music sadder than those with greater left frontal activity.²⁵²

We know that greater right than left parietal activation at rest predicts a better performance on visuo-spatial reasoning, and greater left than right parietal activation at rest a better performance on verbal reasoning tasks.²⁵³ In keeping with this, we also know that the ability to generate visual designs quickly and fluently is strongly associated with the right frontal

lobe, whereas verbal fluency is strongly associated with the left frontal lobe.²⁵⁴ It is striking that experimentally inducing negative affect seems not only to increase activity in the right frontal pole, but the capacity to think visuo-spatially; and inducing positive affect leads to both left frontal activation and increased verbal fluency. The cognitive changes accompany, and appear to be secondary to, the emotional changes.²⁵⁵ This picture is in keeping with the obvious differences between manic states, in which individuals are euphoric, words (whether meaningful or not) tumbling forth like a lava stream, and depressive states in which language seems to desert its victims, who become monosyllabic or mute. Melancholy has been associated with wisdom, scholarship and solitariness:²⁵⁶ but also with silence. Cesare Ripa's Melancholicus shows him thinking, but not speaking: he is reading a book and his mouth is gagged. ²⁵⁷

Fig. 24. 'Melancholicus' (detail) (from the Iconologia of Cesare Ripa, originally 1593, first illustrated 1603: here from the engravings by Gottfried Eichler for the Hertel edition of 1758-60: Part V, 109)

Since we have noted that thinking in images, models and analogies is a prerequisite of creativity, while thinking in words is not (and may actually inhibit creativity at the truly generative stage, rather than at the later more consciously critical stage), it might be expected that mood changes that promote the right frontal cortex will be associated with creativity in a way that those engaging primarily the left frontal cortex will not.

What is the evidence for a connexion between creativity and mental illness? The full story may be complex, but one thing is sure: that it has been debunked is another of the myths that needs debunking. Some people believe there is nothing in it, certainly, but others have good grounds for being equally sure that the idea is importantly revealing.

Before we go any further, please note that it is not a telling observation that some creative people show no signs of mental illness whatever, while others are mentally ill without being creative. I say this because it is solemnly repeated in the literature as though it had some logical force in relation to the point at issue, which is whether mental illness is over-represented amongst creative people. At the risk of stating the obvious, for there to be a highly significant relationship it does not have to be obligatory in either direction. This prejudice against broadly true generalisations, on the basis that we can all think of examples that don't conform, is one of the prevalent fallacies of our age. All knowledge is uncertain, but not *therefore* invalid.

The other prevalent fallacy also arises from the fear of uncertainty, and also applies here. According to this fallacy, the fact that problems of definition make a phenomenon hard to deal with neatly and precisely demonstrates that therefore any intuitively likely conclusion, accepted in some cases for centuries, is *mistaken*. Of course it shows no such thing. All it shows is that the intuitively likely conclusion cannot easily be proved. But neither can many – perhaps all – of our beliefs regarding the most important human concerns. All approaches are open to challenge, but it would be mindless to dismiss all approaches to important questions on that basis. It smacks of the narrow-mindedness of the left hemisphere. On this basis no-one would ever be allowed to have fallen in love. You can imagine the fuss. What does it mean exactly to 'fall in love' – what counts and what doesn't? Should we rely on self-report, with all the attendant problems, or should we not measure something? If so, what? How many subjects should we study? Who would count as control subjects? Whose judgment do we trust? Presumably no-one's? So, we gravely conclude, the concept is meaningless, and the phenomenon an illusion. The left hemisphere simply ignores, dismisses, and ultimately denies the existence of, anything it can't pin down and measure.

Turning to the point at issue, whether there is a relationship between creativity and mental illness, one approach to the question has been to

assess prominent creative individuals historically, an approach that is clearly dependent on the quality of the information available, but not a hopeless situation for all that. Such studies depend on personal judgment, but while we should undoubtedly strive for the most reliable methods, how superior, actually, are the supposedly objective alternatives we have developed at identifying what we are interested in? In any case, on this basis Cesare Lombroso, Francis Galton and Wilhelm Lange-Eichbaum among others, all explored and confirmed the apparent excess prevalence of mental abnormalities, particularly affective disorders, amongst ‘geniuses’.²⁵⁸ Havelock Ellis, one of the first to try a comparatively objective method, namely selecting the 1,030 people whose entries in the *Dictionary of National Biography* rendered them eligible for study, did not find any elevated rate of mental disorder, but, as has often been pointed out, few of the worthies included in his study were geniuses by any stretch of the imagination.²⁵⁹

In our own time the psychiatrist Felix Post studied 291 eminent scientists and inventors, thinkers and scholars, statesmen and national leaders, painters, sculptors, composers, novelists and playwrights for whom adequate biographical information was available, and found the artists and writers to have high rates of affective disorders and alcoholism.²⁶⁰ Psychoses were not especially common, and, where evident, were entirely restricted to affective disorders (depression and bipolar disorder), not schizophrenia. He concluded that, unlike schizophrenia, ‘depression and alcoholism are causally linked to some kinds of valuable creativity’. It is a common experience, confirmed by research, that alcohol can enhance insight-solving, but not analytic-solving.²⁶¹ Reliance on alcohol is, of course, also a common accompaniment of affective disorders, sometimes thought of as ‘self-medication’ for anxiety and low mood.

Another retrospective review of creative artists found ‘a much higher rate of mood disorders in artistic populations than could be expected from chance alone’.²⁶² A review of composers over three centuries reached similar conclusions.²⁶³ A book-length, in-depth review of 195 historical writers, artists, and composers by Kay Redfield Jamison reached the conclusion that depression, cyclothymia (which could be considered an attenuated form of bipolar disorder) and bipolar disorder were unusually common (about 8–10 times commoner) in such individuals.²⁶⁴ Looked at

the other way round, rates of creativity are abnormally high in individuals with affective disorders and their relatives.²⁶⁵

Another approach is to study closely a group of living subjects. A combined historical and contemporaneous analysis suggested that affective disorders were prominent amongst writers and artists, especially bipolar disorder.²⁶⁶ Nancy Andreasen has repeatedly studied The Iowa Writers' Workshop (a famous graduate-level creative writing programme in the United States with many celebrated poets and writers among its alumni); her final study consisted of 30 subjects and 30 controls.²⁶⁷ Rates of mood disorder 'were extremely high in the writers'. She found that 80% (compared with 30% in the control group) had some type of mood disorder, 37% (compared with 17%) had major depressive disorder, 43% (compared with 10%) had bipolar disorder, and 30% (compared with 7%) suffered from alcoholism.²⁶⁸ It is somewhat ironic that Andreasen's research is now stigmatised for relying on painstaking hours of interviewing subjects, and the subsequent application of research criteria – probably the method that provides the highest levels of sensitivity and specificity, although inevitably she was not blind to subject identity. In a study of 47 contemporary subjects, selected for having received a prestigious creativity award, Jamison compared novelists, poets, playwrights, artists and biographers, and, in an attempt to obviate personal judgment, used the criterion of having received treatment for a mood disorder.²⁶⁹ The rate of treatment for affective illness was 'strikingly high' (38%) given that the lifetime prevalence for bipolar and unipolar disorders in the general population are 1% and 5% respectively.²⁷⁰ Poets had the highest rate of requiring medical treatment for mood disorder (50%); they were also the only group to have received treatment for mania (a relatively small subset of the sample). Given that many episodes of mood disorder never reach medical attention, and more antidepressants are prescribed to females than males, while the sample of writers was largely male, the results are, as Jamison points out, still more striking. Biographers, by contrast, 'who provided a comparison group by being outstanding but perhaps less creative writers', reported no history of mood swings or elated states, and a lower rate (20%) of medical treatment for depression.²⁷¹

James Kaufman, in a study of 1,629 writers, found that poets, particularly female poets, were particularly likely to suffer from mental

disorders.²⁷² In a follow-up study examining 826 Eastern European writers of all kinds over 1600 years he again found that poets had higher rates of mental disorders than other types of writer.²⁷³ A study by Arnold Ludwig of over 1,000 eminent people found bipolar disorder, schizophreniform psychosis and depression to be over-represented in the creative arts group.²⁷⁴ A later study by the same author of 59 living female writers compared with 59 matched controls found high levels of depression, anxiety and substance abuse in the creative group.²⁷⁵ Other reviews of living artists of various kinds support this conclusion.²⁷⁶ One study of over a million people carried out at Sweden's prestigious Karolinska Institute found a significant correlation between those in creative professions and mental illness (in particular depression, anxiety, bipolar disorder, schizophrenia, and substance abuse), and demonstrated an increased likelihood of death by suicide.²⁷⁷

Suicide is a relatively rare event, accounting for about 1 in 10,000 deaths in contemporary Britain, slightly more in the US.²⁷⁸ If you have an impression that creative artists are more likely than average to kill themselves, you might be right. There is, of course, nothing scientific about Wikipedia, but it has the advantage of being a fairly representative compendium of figures that have achieved a degree of distinction across a very wide range of activities and professions. It might be indicative that it lists 158 poets, 69 painters and sculptors, and 55 composers who are known to have killed themselves (it has a separate category for unconfirmed but suspected suicides). This compares with 19 academics and eight critics.²⁷⁹ For 158 suicides in poets to be expected, there would have to be Wikipedia entries for about 1,580,000 poets. As far as I can tell there are 2,386.

One might ask how it is that poets, whose chosen medium is language, are so highly represented among those who suffer from depression. Does that not undermine my association of creativity, depression and the *right* frontal cortex? I do not believe so. Poetry is precisely the use of language to transcend the ordinary limitations of language: it relies heavily on metaphor as opposed to literal statement, on implicit connotative meaning as opposed to explicit denotative meaning, on the musical aspects of language and on an empathic ability to enter into the mind of another, all of which skills are ultimately dependent mainly on the right hemisphere, and may even require relative effacement of the fluent left frontal cortex. It is also about

uncommon insight into the nature of reality, into the depth of human feeling and experience – all better achieved by the right hemisphere than the left, as we shall see in due course; and against all of which the cheerful optimism of the left hemisphere is a terrific anaesthetic. Boswell reports, in his *Life of Johnson*, an old schoolmate of Johnson's, one Oliver Edwards, saying, 'You are a philosopher, Dr Johnson. I have tried too in my time to be a philosopher; but, I don't know how, cheerfulness was always breaking in'.²⁸⁰ No impediment, actually, to a philosopher of the modern Western academic variety, but an impediment no doubt to what Edwards had in mind by one – someone closer to a poet than a pedant. The only scanning study of which I am aware to date comparing the reading of poetry with reading of prose reveals that regions of the right hemisphere are engaged by poetry that are not engaged by prose, in particular the right temporal pole and posterior cingulate cortex, and that 'the emotional charge of literary texts is mediated by similar brain structures to the emotional charge of music, particularly involving the right hemisphere.'²⁸¹ The same right temporofrontal regions participate in both musical rhythm and verse metre processing.²⁸²

Incidentally, it is also a common observation – which means, naturally, that while quite probably right, it will prove a test of ingenuity for some kinds of psychologist to 'prove' it wrong – that there is a high rate of mental illness in comedians. A roll call of contemporary comedians known to have suffered from depression includes Woody Allen, Lenny Bruce, Graham Chapman, John Cleese, Peter Cook, Tommy Cooper, Tony Hancock, Kenneth Williams, Spike Milligan, Dudley Moore, Richard Pryor, Victoria Wood, Robin Williams, Stephen Fry, Ruby Wax, Jack Dee, Caroline Aherne, David Walliams, Mark Watson, Graham Fellows, Peter Sellers, Sarah Silverman – and many others. An investigation of 523 individual comedians contrasted with actors concluded that, like other creative individuals, they commonly displayed 'the personality equivalent of bipolar disorder, corresponding to what in an older personality literature would have been termed "cyclothymic temperament"'.²⁸³ We have already seen that sense of humour is highly dependent on right frontal function, to the extent that those with lesions in this area cannot understand jokes or humorous cartoons; and that comedians' creative use of connotative and ambiguous language, and reliance on only partially stated meaning, have many overlaps with poetry.

But, it might still be asked, how is it that depression could in *any* form be associated with creativity – depression that is usually marked by complete lack of fluency and motivation? This is a pertinent question. Resolving that paradox depends on being clear about both the timing and the degree of the affective disorder. For in fact very few poets have been particularly creative when in the throes of mania, with its *excess* of fluency and motivation, any more than in the throes of depression. It may be that having the disorder promotes creativity, though its more extreme expressions inhibit it while they prevail. A study of 24 manic-depressive artists found that, while a quarter reported being more creative untreated with lithium, half reported being more creative when treated with lithium; a quarter found there was little difference.²⁸⁴ Andreasen also suggests that treating bipolar disorder is likely to improve, rather than impair, creativity.²⁸⁵

Similarly, in the depths of despair the muse is likely to desert the creative artist, but the recovery period may be highly fruitful. ‘Among the writers in the Iowa Workshop study’, Andreasen reports, ‘essentially all of them reported that they were unable to work creatively during periods of depression or mania’.²⁸⁶ It is the later period, during remission, that brings the creativity: ‘For some composers it seems that they are most productive immediately after a phase of depression’, as one study of depression in the lives of 12 composers concludes.²⁸⁷

The economist and statistician Karol Jan Borowiecki used linguistic analysis software to scan the text of 1,400 letters written by Mozart, Beethoven and Liszt to their friends, colleagues and loved ones, and analysed the results for the expression of positive and negative emotions, such as joy, love, grief and heartache.²⁸⁸ He then plotted the course of mood against creative production. The resulting curves are striking: he found a consistent link between the intensity of negative emotions, especially sadness, and subsequent periods of artistic brilliance. He concluded that such sadness was not just correlated with creativity but that it actually had a reliable causal effect, typically delayed by some months.

It is frequently noted that some mental illnesses, such as schizophrenia, are widely distributed and conserved in the world population despite being associated with a high degree of morbidity and vulnerability, reduced life expectancy, and low levels of mating and fertility. This apparently anti-Darwinian trend suggests that, while those who have enough of the genes

involved to bring about the full diagnosable disorder may be at a disadvantage, their relatives, who may share only some of the genes, are at an advantage.²⁸⁹ There is a body of literature that suggests precisely that.

As we have seen, in his study Post found that the mental conditions associated with creativity were by no means principally psychotic and, when they were, were confined exclusively to affective psychoses rather than schizophrenia. Having schizophrenia tends to impede creativity, unlike having an affective disorder. But having some, but not all, the genes for schizophrenia may promote creativity. There are a number of what could be seen as *formes frustes* of the condition, lying somewhere along the schizo-autistic spectrum, but falling short of full-blown psychosis, which seem to be common amongst creative people, in science and mathematics as much as, or more than, in the arts. I would agree that there is, as one paper puts it, ‘overwhelming support for a positive relationship between creativity and schizotypy’, a personality type which shares some features, but importantly not all, with schizophrenia.²⁹⁰ And we saw earlier that schizotypy (unlike schizophrenia) tends to increase some kinds of right hemisphere activity. It has been repeatedly shown that the *healthy relatives* of people with psychotic illnesses such as schizophrenia and bipolar disorder, and who presumably share some traits, are more creative than average.²⁹¹ A study of bipolar subjects, cyclothymes, their well first-degree relatives and controls found that being cyclothymic or a close relative of a subject with bipolar disorder was associated with greater creativity than being severely ill or having no genetic relationship to individuals with bipolar disorder.²⁹² Individuals with bipolar disorder and healthy siblings of people with schizophrenia or bipolar disorder were over-represented in creative professions, according to a study of 300,000 subjects.²⁹³ Indeed a study of artistic creativity, defined very loosely as tertiary education in ‘an artistic field’, uncovered higher rates of hospital admission for each of schizophrenia, bipolar disorder and depression; but the criterion seems to me too loose to be of much value.²⁹⁴ At the genetic level, an Icelandic study of 88,000 subjects found that people in creative professions are significantly more likely to have gene variants that increase the risk of bipolar disorder and schizophrenia.²⁹⁵

Another question that arises is whether induced mood states in ‘normal’ subjects modify cognition in the same way that the mood states of those

with mental illness (or a partial or mild form of mental illness) seem able to do. Right greater than left frontal activation seems to occur during temporarily induced negative emotional states as well as more chronic low moods,²⁹⁶ and to occur whether or not the individual has a diagnosis of a mood disorder.²⁹⁷ Does that have an effect on creativity? It has been found that such induced negative mood can result in improved performance on creative tasks, particularly those requiring concentration, divergent thinking, and analogical problem-solving.²⁹⁸ But the results are not clear-cut or reliable. For example, some right hemisphere cognitive functions appear to deteriorate in depression: one possibility would be that ‘the frontal activity in the right hemisphere represents some sort of inhibitory function that has the effect of suppressing the information processing operations of the right hemisphere during depressive emotion’.²⁹⁹ One of the few research efforts that specifically addressed the need or otherwise for a pre-existing vulnerability found that being subjected to social rejection increased creativity, but did so to the greatest extent in those who were ‘biologically vulnerable to experiencing negative affect’, suggesting that the effects are, perhaps unsurprisingly, a combination of circumstances with pre-existing genetic vulnerability.³⁰⁰

There is, however, another puzzle involved. There is much evidence that negative emotions can lead to creativity, probably by a range of routes: for example, by enhancing contact with a more emotionally rich level of awareness, more broadly ramifying into redolent emotional memory, and involving deep unconscious and embodied cognition, as well as analogical thinking; or by inducing self-reflective thought; or perhaps by encouraging perseverance.³⁰¹ But the picture is highly variable. Some studies have suggested that happiness, rather than sadness, is more creative,³⁰² while other studies report mood as making no difference.³⁰³ How is that?

The answer may be that we are not comparing like with like. It may make a difference what stage of the creative process we are talking about (positive mood may be a help when dealing with what I have called the later, ‘translational’, phase, but not in earlier phases). It may also make a difference whether we are talking about individuals working alone or in groups: for example, one of the studies that showed positive mood to be more effective was a study of groups not individuals, in which positive mood had an energising effect, as one might expect;³⁰⁴ and another found –

surprise, surprise – that inducing a good mood led to the subjects enjoying their task more.³⁰⁵ Furthermore, not all so-called negative (in reality often valuable) moods or positive (in reality often negligible) moods are alike. In creativity tests, where mood was induced by showing film clips, amusement, on the positive side, broadened attentional focus, while appetite narrowed it; on the negative side, sadness broadened it, while disgust narrowed it. ³⁰⁶ Amusement and sadness were associated with greater creativity than appetite and disgust. Sadness is more right hemisphere-related, disgust more left hemisphere-related.³⁰⁷

Mind you, one of the many artificialities of such studies is that they imagine that human beings experience largely simple emotions, rather than complex ones fraught with ambivalence. Such ambivalent emotions may be more important in creativity, another possible reason for conflicting results in the literature assessing emotional ‘valency’.³⁰⁸

It may also make a difference what type of creative work we are considering. A study of Goethe’s moods in relation to creativity found that poetic inspiration and insight came to him when he was psychologically labile, even clinically depressed, while

Goethe’s scientific and social activities and achievements were associated with personal well-being, but also with lack of poetic inspiration ... Goethe’s depressive moods were associated with eminent poetic creativity whereas in times of scientific and political productivity Goethe seemed to be protected against depressive episodes.³⁰⁹

But, most importantly, it may make all the difference whether we are talking about creativity with a ‘little c’ or with a ‘big C’. Paradoxical though it may seem, our desire for objectivity may make it harder for us to reach the truth, since, if the phenomenon itself is both rare and (when it exists) hard to study, it may be tempting to study something that looks like it, but is commoner, and easier to pin down. The only problem with this is that you are now studying something completely different. There may be all the difference in the world between run of the mill ‘creativity’ and that of the genius.

Dean Keith Simonton has written about and researched geniuses for many years. He argues that there is a distinction to be made between ‘everyday’ creative people, identified as such perhaps because they work in a science research department or as a photographer, and the once or twice in a generation, highly creative, geniuses. While everyday creativity probably leads to improved satisfaction, self-esteem and enjoyment of life, really pushing the boundaries may come at a price. He calls this the ‘mad-genius paradox’.³¹⁰ There is a potential parallel here with a finding we have already seen. Nine of the studies cited by Dietrich & Kanso showed something fascinating that their dismissive overview failed to spot: that ‘averagely creative’ individuals tended to engage primarily the left hemisphere in a creative task, whereas highly creative individuals tended to engage the right (see Appendix 1). They took this to be a ‘null’ result, but it is the opposite. This would also cohere with the finding reported by mathematicians such as Anna Sfard or Vadim Krutetsky that children averagely skilled in mathematics use serial (left hemisphere style) procedures to reach their results, whereas gifted children use analogical (right hemisphere style) thinking; as well as with the findings that those of the highest (verbal, as well as spatial) ability rely more on their right hemisphere.³¹¹

On this topic of making sure that you are really looking at the highly creative subjects, a study showed that ‘normal scientists’, those that are concerned with preserving the paradigm, and ‘revolutionary scientists’ whose work transcends the paradigm, have quite different profiles. While the paradigm-preserving, ‘normal’, scientists had lower than average levels of mental illness, the paradigm-rejecting, ‘revolutionary’ scientists had higher than average levels – in this respect resembling poets and artists.³¹²

As we have seen, there is a relationship between intelligence and creativity, particularly at higher levels. There is also a relationship between the right hemisphere and intelligence, which was explored in a previous chapter. But is there a relationship between intelligence and mood disorders?

A study of every school leaver in Sweden over a 10-year period found that excellence in academic achievement at school was associated with later development of bipolar disorder,³¹³ as did a British prospective study with over 15,000 participants.³¹⁴ A study of one million men found that men with the highest intelligence had higher rates of bipolar disorder.³¹⁵ Another

study of over 50,000 male subjects, however, found no relationship between higher intelligence and mental illness of any kind.³¹⁶ Catherine Weismann-Arcache, who studies gifted children, argues for the relationship between high intellectual potential and depression, using both historical and contemporary evidence. She and her colleagues found that, according to DSM-IV-TR criteria,³¹⁷ major depressive disorder was found in 65% of the 100 children with very high intellectual potential that she studied, a rate 10–20 times higher than would be expected for their age.³¹⁸ However, a thorough and thoughtful survey of the area by Maureen Neihart concludes that, while there are some correlations between adult psychological disorders and high IQ and creativeness, the literature on depression does not support a correlation between high IQ and depression among children and adolescents *per se*. She does conclude, however, that there is ‘clear evidence’ that creatively gifted adults, writers in particular, commit suicide at rates higher than the general population.³¹⁹

There are probably several factors involved. James Webb at the Davidson Institute for Talent Development suggests that exceptionally gifted young people are more prone to existential depression, in brief because they have greater insight, and question things that many people take for granted.³²⁰ They may feel they don’t fit in as well as other children, may subject themselves to greater pressure to succeed, and may have higher ideals. On the other hand, they may be better able to adapt, because of their insight, and may find greater fulfilment in the use of their talents. This would fit with the finding that higher IQ means a higher risk of a lifetime diagnosis of depression, but also a better level of mental health at age 50.³²¹ The obvious truth that depression can, especially during an acute episode, impair cognition and lower scores on IQ might mask a positive association between depression and intelligence.³²² And, finally, it may matter what you mean by ‘high’. One interpretation that would fit with the data is that low IQ may be associated with depression, while ‘averagely high’ IQ (around 120) may be protective against depression, and ‘super high’ IQ (over 150) may be once more associated with depression.³²³

SUMMARY

Creativity involves a number of elements in which the right hemisphere is superior to the left: breadth of vision, the capacity to forge distant links, flexibility rather than rigidity, a willingness to respond to a changed, or changing, context, a tolerance of ambiguity, and an ability to work with knowledge that is, for the most part, inherently both imprecise and implicit. It involves analogical thinking and visualisation; it is often expressed in music, metaphorical and original language, and visuo-spatial imagery, all of which are also better served by the right hemisphere than the left. It can easily be inhibited by too close following of rules, too familiar patterns of thought, a requirement for certainty and clarity, and a concern for detail too early in the process, all of which tend to be favoured by the left hemisphere. Thus, though the left hemisphere has a role to play during the later implementation of a creative insight – what I call the translational phase – it tends to impede during the generational and permissive phases, which correspond to what most people mean by creativity. There seems to be a marked increase in reliance on the right hemisphere among the highly creative, compared with the averagely creative, and not observing this distinction in experimental design has sometimes muddied the waters of research into hemispheric differences. Nonetheless, there is a very large body of evidence suggesting that the right hemisphere plays the key role in creativity.

WHAT SCHIZOPHRENIA AND AUTISM CAN TELL US

Metaphysicians do not readily descend from the heights whereon they love to dwell ... It goes against them to come into touch with minute facts, especially with such facts as mental maladies for example: they would be afraid of making their hands dirty.

—*Henri Bergson*¹

AN IMPORTANT PART OF THE THESIS BOTH OF THIS BOOK AND ITS predecessor is that we have come to see and inhabit the world in a most peculiar way: one whereby what can be offered by the right hemisphere, the one that sees and understands most, has come to be neglected, with consequences that are far-reaching – indeed devastating. In the previous chapters of Part I we have looked at aspects of hemisphere difference, facet by facet, often by examining cases in which there is literal brain damage. Since hemisphere imbalance changes what we find in the world, and since the rest of this book is about how we can arrive at some degree of truth towards and about the world delivered by the bipartite brain, it would be invaluable to get an idea of what the world actually feels like overall for a person with such an imbalance – how it actually *is* for them; to get the ‘inside’ story. We might recognise tendencies, if nothing more, in our culture and in ourselves, and thereby be on guard when we find this is how the world is coming into being for us, too.

‘Illness is philosophically revealing and can be used to explore human experience’, writes the philosopher Havi Carel:

I suggest that illness is a *limit case* of embodied experience. By pushing embodied experience to its limit, illness sheds light on normal experience, revealing its ordinary and therefore overlooked structure. Illness produces a *distancing* effect, which allows us to observe normal human behaviour and cognition via their pathological counterpart. I suggest that these characteristics warrant illness a philosophical role that has not been articulated.²

Except perhaps by William James, who as in everything was so much before his time. ‘Insane conditions have this advantage’, he wrote,

that they isolate special factors of the mental life, and enable us to inspect them unmasked by their more usual surroundings. They play the part in mental anatomy which the scalpel and the microscope play in the anatomy of the body.³

Mental illnesses and brain diseases are sometimes discussed as though they were like mechanical faults. But they are not. It’s not that the mind ‘doesn’t work’ properly, as if a component has ceased to function. In the first place, when something is altered in the brain or the mind, it is never just a component, inert and isolated. Brains and minds are living, constantly adapting, interconnected systems. And they are conscious. A brain disease or mental illness, then, is a change in a *person’s* whole way of being in the world.⁴

The phrase ‘way of being in the world’ may seem a bit mannered, but I can’t think of a good substitute. It isn’t just about thinking differently, or feeling differently, or behaving differently, though each of those is an important part (and each is bound up with the others). It involves a difference in the type of *attention* paid to the world. It is about having a whole different take on the world, a different disposition towards the world, in which certain features stand forward and others inevitably recede. In that disposition, one’s perceptions, thoughts, emotions and responses are all bound up together in a way that makes sense as a whole – even if, for some individuals, the way in which they make sense is by supporting the view that nothing makes sense at all.⁵ Diseases of the brain and mind, though disruptive and distressing for the individuals who have to suffer them, offer

us rare insights into human experience as a whole, for which we should be grateful. They throw into relief our normal reality by showing us how it could be altered and appear quite differently to us.

So how are we to get an insight into such a way of being? For this we would need personal accounts. As the reader will have seen, one of the common features of right hemisphere damage is that the individual denies that there is a problem: thus there are relatively few accounts from the inside. Accounts are usually *of* the patients, not by the patients themselves. Moreover, neurologists and neurosurgeons are mainly not concerned with alterations in phenomenology, so tend not to ask the questions that a psychiatrist might ask, and their patients are not likely to volunteer the information unbidden.

Not all subjects with altered brain function, however, fit this picture. Schizophrenic subjects, for example, often, similarly, deny that they are ill, but they are somewhat less likely to deny their experiences (though they may), and can at times be notably articulate about them: added to which psychiatrists spend a lot of time talking to them and often write conversations down. That in itself would, of course, be of little relevance here, were it not for the quite remarkable parallels between schizophrenia and right hemisphere deficit states, as I shall shortly demonstrate. There are undoubtedly different qualities to the experience of schizophrenia and that of right hemisphere damage, and there is no simple equation to be made between the two (each of which having, in any case, a variety of manifestations). Nonetheless, it is striking how each and every aspect of the *breakdown of reality* in schizophrenia that we will now be dealing with is paralleled by what in a non-schizophrenic individual would indicate a recognised typically right hemisphere, not left hemisphere, deficit.

While schizophrenia and autism are distinct conditions, they have many overlapping features, as well as sharing a genetic basis.⁶ And in what follows I will show that autism, too, in its most characteristic form, simulates many right hemisphere deficits.⁷ Disturbances of language are also, obviously, part of the phenomenology of schizophrenia, and autism, and they would normally follow left hemisphere deficits, so both hemispheres are affected; but I am concerned here with the breakdown of *reality*, which language exists to help represent, not with language in itself.

In the first part of this chapter, then, I will explain why these conditions can be assumed to give us a pretty good general idea of what it is like to

inhabit a left hemisphere-dominated world. And then I want to take a closer look at some of the particular aspects of the experienced world that come to be altered from the accounts of patients themselves.

I must stress that the reader should as far as possible abandon the standpoint of seeing these as merely pathological ‘distortions of reality’, even though they are also that (and that is how, as a physician, I would treat such an account in diagnosing schizophrenia). Rather, the reader should strive to see it instead as an authentic account of a real aspect of the world *as it comes into being* for someone largely dependent on the left hemisphere. Since all that any of us has to go on is our experience, this is how the world actually *is* for someone when the various alterations in attention, perception, judgment and so forth which we have discussed come together. Since the subject cannot know what he or she doesn’t know, it is fruitless arguing with a deluded patient: their reality demonstrably does not coincide with the best-evidenced view that we can take, and so we are quite right to think them mistaken, but for them their experience is authentic, and more compelling, than any argument. And what the subject with schizophrenia, particularly, experiences is a very alarming world. It is a take on the world that we can all approximate, in the absence of schizophrenia, if we become sufficiently dependent on the left hemisphere alone.

I suspect the reader may well conclude that there are similarities with the world we *are* bringing into being around us. Three functions that are to a very large degree right hemisphere-dependent, as the reader will know, are sustained attention, the ability to read faces, and empathy. All three are impaired in schizophrenia and in autism.⁸ And impairments in all three are increasingly being found in the younger ‘normal’ population today. But the parallels are far more numerous than such a snapshot might suggest.

Is it conceivable that elements of the way of being in the world embedded in a culture might start to resemble one hitherto largely confined to the mentally ill? This is, in fact, the argument of one of the most fascinating, and compelling, books I have ever read, *Madness and Modernism: Insanity in the Light of Modern Art, Literature and Thought* by Louis Sass, Distinguished Professor of Psychology at Rutgers. Published in 1992, and

by now a classic, the book has a riveting thesis. Sass had noticed that every phenomenon described by people with schizophrenia bore a close resemblance to phenomena not just found in, but at the core of, modernism; and in the book he illustrates his thesis in detail, across numerous domains, drawing with subtlety on a deep familiarity with the literatures of psychology, philosophy and the arts. Moreover, as he demonstrates, a surprisingly large number of people who rose to prominence in the worlds of literature, art, music and philosophy during this period (but not nearly so commonly in other periods) were on the schizo-autistic spectrum. The closeness of the parallels he draws, across so many instances, makes the similarity difficult, if not impossible, to deny. The question is, why should this be? Clearly a whole culture cannot develop schizophrenia.

The answer might lie in an observation Sass alludes to, based on findings then just starting to emerge from the neuroscientific literature, that the phenomena of schizophrenia resemble those described by subjects with right hemisphere damage (coupled with those that would result from a perhaps compensatory overdrive of the left hemisphere).⁹ Might it be, then, that as a culture we were exemplifying not, of course, a sudden epidemic of schizophrenia, but too heavy a reliance on the world as delivered to us by the left hemisphere, meanwhile dismissing what it is that the right hemisphere knows and could help us understand?

SCHIZOPHRENIA AND RIGHT HEMISPHERE DEFICIT SYNDROMES: PHENOMENOLOGY

The confluence of phenomenology between right hemisphere-damaged and schizophrenic patients, both how they perceive the world and come across to others, is extraordinary.¹⁰ We have seen that every kind of visual distortion and hallucination found in schizophrenia is also found in right hemisphere dysfunction, along with auditory, tactile and olfactory hallucinations. As far as delusions go, not merely paranoia, but monothematic delusions such as Capgras and Cotard syndromes are found not just in right hemisphere disease but in schizophrenia.¹¹ Schizophrenic patients are sometimes hard to tell from right brain-damaged subjects. For example, they were ‘statistically identical to patients with right brain damage and robustly different from those with left brain damage’ when compared on a test of social and emotional interpretation and expression.¹² Schizophrenic patients are almost indistinguishable from right hemisphere-damaged patients in failing to deal with the connotative or metaphorical, rather than the denotative and literal.¹³ A patient who had had his right hemisphere surgically removed was asked to draw a human being: an expert blind to diagnosis commented that many features of the drawing ‘strongly suggest schizophrenia’. ¹⁴

Subjects with right hemisphere damage and subjects with schizophrenia share many common characteristics. Right hemisphere-damaged subjects demonstrate impairments in the sense of the unity and integrity of the body; fragmentation of bodily awareness is associated with right hemisphere, especially right frontal, dysfunction.¹⁵ They have impairments in perceiving and recognising bodies and bodily movements – indeed biological motion of any kind;¹⁶ and can exhibit a startling inability to recognise their own face, parts of their own bodies or their body as a whole.¹⁷ All of these are well-described phenomena in schizophrenia (and in some cases in autism; see notes).¹⁸ But, while these, along with delusions and hallucinations, are some of the more dramatic and well-known features of schizophrenia, at the core of the condition lies a host of much subtler changes that are in a way

more troublesome, and these are also highly characteristic of people with right, but not left, hemisphere damage.¹⁹

Both those with right hemisphere deficits and those with schizophrenia tend, for example, to exhibit emotional indifference, passivity and lack of initiative.²⁰ Both show diminished expressivity in, and receptivity to, facial expressions, vocal prosody (expressive and receptive understanding of intonation) and bodily gestures.²¹ Both groups tend to neglect context, and therefore have difficulty appreciating the ‘discourse elements’ of communication. Both find narrative difficult to understand,²² and difficult to generate.²³ Both complain of being unable to read a book or watch a film, because they cannot integrate the storyline over time.²⁴

Both tend to confabulate.²⁵ Both have deficits in pragmatics, the overall understanding of the meaning of an utterance in context. They have similar problems in dealing with the implicit – not just tone of voice, but tone of any kind, including humour, irony or sarcasm;²⁶ facial expressions and body language; and other implicit processes such as understanding metaphor.²⁷ They rely on the explicit and literal. Both are relatively limited in the expression and interpretation of emotion. Both have difficulty being flexible in their views or patterns of behaviour; both can encounter problems in understanding another’s point of view, and in ‘theory of mind’, the capacity to see that what another person knows may be different from what you know.²⁸

They have similar problems with *Gestalt* perception – seeing the whole; and similar attentional deficits, particularly in sustaining attention over time.²⁹ A cardinal feature of schizophrenia is the inability to sustain the all-important sense of the whole. ‘The most plausible psychological theory of [schizophrenia’s] nature is a breakdown in *Gestalt* and the most plausible biological theory involves some degree of hemispheric imbalance’, argue John Cutting and Francis Dunne.³⁰ Schizophrenic subjects have a reduced capacity to see the whole pattern;³¹ they respond faster to local targets;³² and tend to adopt a ‘piecemeal’ approach in the description of complex images.³³ Out of 60 reviews of this area in the literature to 2010, 55 found that dysfunctional perceptual organisation, particularly deficits in appreciating the broader picture and contextual information, were highly characteristic of schizophrenia and probably underlie other aspects of the condition; as well as constituting in themselves a serious handicap, which

on its own predicts poorer long-term outcome.³⁴ As the review authors point out, in such subjects there is a ‘widespread deficit in the generation of contextually co-ordinated neural activity across both space and time’.³⁵ Full appreciation of space and time is highly dependent on the right hemisphere as we have seen, and will see further in Chapters 22–4, and both tend to be widely aberrant in right hemisphere dysfunction.

Perception is not a mosaic of independent responses to local stimuli, but involves constant interactions, back and forth, between local stimuli and the context, as well as one another; understanding the resultant wholes is what makes sense of the world.³⁶ In schizophrenia, the object in itself tends to become isolated, focussed on at the expense of the context.³⁷ When a perceptual task can be carried out piecemeal and solely from the bottom up, schizophrenic subjects and those with schizophrenia spectrum disorders perform relatively normally.³⁸ Their perception is impaired in proportion to the degree to which the experimental task requires one to go back and forth between the local level and that of the whole that is *itself in the process of coming into being*.³⁹ One theory is, indeed, that it is more the capacity readily to shift from one attentional level to another that is impaired, than a problem of global or local attention *per se*;⁴⁰ and the reader will be familiar with the idea that left hemisphere attention is less flexible. It should not be forgotten, however, that to see the whole in itself already requires seeing parts and whole together: appreciation of both a context for everything and of everything in its context.

When you can no longer perceive the whole *as* an indivisible whole, it breaks up into a mass of mere meaningless *things*. Not seeing the whole means that you don’t see the context; and one way of looking at it is that such a deficit is ‘but one manifestation of a widespread impairment in cognitive co-ordination – the grouping of information based on *contextual* relationships’.⁴¹

Deficits in context appreciation may be central to a number of cognitive problems experienced by schizophrenic subjects.⁴² And since this is a matter of attention, not just vision, problems with understanding context occur in other modalities,⁴³ such as audition, and of course in language comprehension.⁴⁴ In other words, difficulties occur right across mental space, not just physical space.⁴⁵

As a corollary, schizophrenic subjects are actually better than normal subjects in a situation where seeing the whole interferes with seeing a part,⁴⁶ and in laboratory situations where context is set up to be misleading, as in certain visual illusions to which neurotypical individuals are susceptible, schizophrenic and autistic subjects are relatively resistant to the illusion.⁴⁷

Both right hemisphere-damaged subjects and schizophrenics, intriguingly, lack an intuitive sense of the reality or substantiality of experience, sometimes feeling that it is all ‘play-acting’. Both can experience a loss of the sense of the unique person, place or object. Above all, they have a similar lack of what might be called common sense. Two statements most commonly endorsed by schizophrenics were: ‘I cannot immediately recognise other people’s faces’ and ‘I have no common sense’,⁴⁸ both of which refer to capacities that are highly right hemisphere-dependent. And, as I wrote in *The Master and his Emissary*, in both groups

there is a loss of the stabilising, coherence-giving, framework-building role that the right hemisphere fulfils in normal individuals. Both exhibit a reduction in pre-attentive processing and an increase in narrowly focussed attention, which is particularistic, over-intellectualising and inappropriately deliberate in approach. Both rely on piece-meal decontextualised analysis, rather than on an intuitive, spontaneous or global mode of apprehension. Both tend to schematise – for example, to scrutinise the behaviour of others, rather as a visitor from another culture might, to discover the ‘rules’ which explain their behaviour. The living become machine-like: as if to confirm the primacy of the left hemisphere’s view of the world, one schizophrenic patient described by Sass reported that ‘the world consists of tools, and ... everything that we glance at has some utilization’.⁴⁹

Significantly, it has been noted for years that one of the underlying mental habits of schizophrenic patients, as in right hemisphere-damaged patients, is jumping to conclusions (and delusional reference to the self).⁵⁰ Indeed a delusion could be seen as a conclusion that has been jumped to on little or no evidence, and has then *stuck* (both the jumping to conclusions

and the ‘stickiness’ are suggestive of left hemisphere involvement). Nearly half of all people with delusions jump to conclusions at the least suggestion, demonstrating ‘an extreme data gathering bias’.⁵¹ It has been suggested that the extent of this phenomenon is a predictor of (poorer) prognosis and response to treatment among those with psychotic illnesses.⁵²

In keeping with the stickiness of the left hemisphere that we have already observed, in schizophrenia images persist for longer;⁵³ and the attentional blink, prolonged in right hemisphere damage, is also prolonged in schizophrenic subjects.⁵⁴ I mentioned earlier that stickiness of gaze, getting locked onto a target, occurs in both right hemisphere damage and schizophrenia. By way of illustration, a schizophrenic patient says: ‘Sometimes an object really seems to stand out from the rest of what I see. My eyes then fix on it. It’s like being spellbound, even though I don’t want to look at it at all.’⁵⁵

Finally, some evidence that tends, if no more, to confirm the picture comes from a large study of somatic delusions in psychotic illnesses, in which John Cutting and I analysed the bodily delusions, hallucinations and misperceptions of 550 psychotic patients (250 with acute schizophrenia, and 100 each with chronic schizophrenia, depression and mania).⁵⁶ We identified 37 sub-categories of delusions affecting 40 parts of the body. As part of the study we examined lateralisation of delusional phenomena: in schizophrenia, where a single side of the body was specified, in over 80% of cases it was on the left, suggesting right hemisphere dysfunction. (A case familiar to the public, not studied by us, was that of John Nash, subject of Sylvia Nasar’s *A Beautiful Mind*, who believed he was the *left foot* of God.)⁵⁷ In depression, on the other hand, there were six cases where the side of the body was specified, and there every one of them was located on the right side, suggesting left hemisphere dysfunction (a known association of depression). This is in keeping with other research in the area.⁵⁸

The differences were not, however, just in the location, but the nature, of the patient’s reported complaint. In schizophrenia, the complaint was, in a fashion characteristic of the left hemisphere, both very detailed and very bizarre: half the spleen was missing, body parts were made of glass, there was an aeroplane glued in her ear, an extra arm growing out of his chest (imagery suggestive of the work of a twentieth-century Hieronymus Bosch). It is also often technical: it is a consistent observation of mine that

when a patient talks of his or her ‘brain’ rather than his or her ‘mind’, the diagnosis is more likely to prove to be on the schizo-autistic spectrum.⁵⁹ By contrast, all the delusions in depression, where there was presumed left hemisphere dysfunction, referred in an understandable way, characteristic of the right hemisphere, to the mind, and did so in an appropriately non-specific way – ‘something wrong with the right side of my head’, ‘mind not working on the right side’, and so on.⁶⁰ Depressive delusions in general concern *malfunction*, usually of the head, or mind, but also of the bowels: close enough to reality (since both depression and its treatments have effects on bowel function), and certainly understandable, even if not strictly the case. They are to do with the *process* of a *whole*. On the other hand, schizophrenic delusions, being left hemisphere-driven, generally concerned gross *structural* changes, and these changes were to body *parts* – and are not generally understandable.⁶¹

SCHIZOPHRENIA AND RIGHT HEMISPHERE DEFICIT SYNDROMES: BRAIN CORRELATES

First, an important caveat that needs to be taken into account when deciding how to weigh lateralised findings, especially from neuroimaging, in schizophrenia. Despite its importance, it has not been sufficiently discussed in the literature. The similarity between schizophrenia and right hemisphere damage does not necessarily imply that individual schizophrenics simply do have deficits in their right hemisphere or overactivity in their left hemisphere – *precisely because one characteristic feature of schizophrenia is that the brain is no longer lateralised in the normal way*. The hemisphere that is situated on the right may be functioning for this patient rather more like a left hemisphere, and vice versa; or, most probably, each may incorporate aspects of the functioning of both hemispheres. This makes evidence on lateralisation at the level of anatomy or physiology in schizophrenia harder to interpret than the phenomenology.

The picture, then, is complex and abnormalities are certainly not confined to one hemisphere. That said, schizophrenic subjects, and even their first-degree relatives in some cases, do show a wide range of structural abnormalities in the right hemisphere, especially in frontal and parietal areas; the interested reader is referred to the notes here for further detail.⁶² Hallucinations and disturbances of the self in schizophrenia are particularly associated with right frontal and parietal regions.⁶³ Disruption of communication between the right hippocampus and orbitofrontal cortex has been implicated in the pathogenesis of delusions in schizophrenia.⁶⁴

Some characteristic neuropsychological deficits in schizophrenia are associated with right frontal hypometabolism,⁶⁵ not to mention biochemical⁶⁶ and electrophysiological⁶⁷ abnormalities in the same region, and in the right hemisphere more widely; and a brain dysfunction centred on the right temporal region has been found to characterise treatment-refractory schizophrenics.⁶⁸

There are marked differences between gene expression in the right frontal pole and the left frontal pole of the brain in the normal subject. This is related to the expansion of the right frontal cortex relative to the left, the largest anatomical asymmetry in the brain, and is particularly responsible

for greater right-sided neuronal plasticity. There are 35 protein-coding genes expressed in the most anterior part of the frontal cortex (known as Brodmann area 10) on the right, and only five on the left. And here's the thing: 'strikingly, the vast majority of these differentially expressed genes were implicated in pathogenesis of one single disorder: 24 out of 30 genes were disrupted in schizophrenia.'⁶⁹ There are links, then, between the genes involved in producing normal brain asymmetry (via, but not confined to, expansion of the right frontal cortex), and the genesis of schizophrenia. Thus it is of no small interest that in schizophrenia – and in autism – there is a very well-attested loss, or even reversal, of normal hemispheric asymmetry, both anatomically and to some extent functionally.⁷⁰

I mentioned in Chapter 1 that transmission from right hemisphere to left is faster than from left to right. However, this effect is lost, or even reversed, in schizophrenic subjects, possibly because of failure of adequate myelination of the long tracts of the right hemisphere.⁷¹ The degree to which normal brain asymmetry is lost or reversed correlates with the severity of what is called the 'disorganisation' syndrome, in which patients are grossly out of touch with reality, whether hallucinating and delusional or not; and patients with hallucinations and delusions, too, show highly significant leftward functional asymmetry in the resting state.⁷²

Equally, loss of the normal anatomical asymmetry is manifest in those areas where there *should* normally be a greater left-sided volume – the areas responsible for language, in the temporoparietal region, especially what is called the planum temporale.⁷³ This is no doubt one factor that is related to impaired linguistic function in schizophrenia. In either direction, then, there are abnormalities of asymmetry which affect differentiated hemisphere functioning.

As the reader has seen, the right hemisphere is largely responsible, in a host of ways, for sustaining the lived world we inhabit, while the left hemisphere deals mainly with a theoretical schema or map – a representation only. So one way of looking at schizophrenia would be this: the subject is struggling with a left hemisphere whose linguistic and conceptual functioning is impaired by the encroachment on it of what should be going on separately in the right hemisphere; and meanwhile the reality-orientated functioning of the right hemisphere is impaired by the intrusion into it of what should be going on separately in the left.⁷⁴ You might think of it as like trying to map what you are living, instead of living

it – and at the same time trying to live in the map. So, yes, language is sometimes awry in schizophrenia. But much more significantly, and more revealingly for us, so is comprehension of the real world.

Interest has also increasingly transferred to problems of interconnectivity *between* regions, rather than simply regions in themselves: to systems rather than modules. Some phenomena characteristic of schizophrenia may result from abnormalities in glutamatergic transmission, or in white matter tracts, or in both.⁷⁵ There are well-known abnormalities of the corpus callosum, the brain's largest white matter structure, in subjects with schizophrenia.⁷⁶ While the precise nature of the relationship between them remains uncertain, to quote one review

it is likely that whatever the cerebral basis of schizophrenia turns out to be, the corpus callosum, the largest connecting tract of the human brain, is bound to reflect this. Similarly, a primary disturbance in [callosal] development will impinge on many other cortical structures.⁷⁷

It is a matter of interest that large white matter tracts, such as the superior longitudinal fasciculus, that integrate functioning between anterior and posterior regions of each hemisphere, come to their full potential only when they are myelinated in the late teens and early 20s – precisely when schizophrenia tends to become manifest. Abnormalities of myelination in schizophrenia are well established; equally, hypofunction of such tracts, principally those of the right hemisphere, has been implicated in schizophrenia.⁷⁸

Meanwhile, left hemisphere hyperactivation has been demonstrated in schizophrenia;⁷⁹ and research on cerebral metabolism has confirmed that individuals on the schizophrenia spectrum tend to overactivate the left hemisphere, relying on it in circumstances in which it would be more usual to rely on the right.⁸⁰ Symptom severity in schizophrenia has been found to correlate with left hemisphere activation. Not coincidentally, the most effective treatment for schizophrenia (and mania) are classes of medication, used across the world for decades, which amongst other things induce a shift in the balance of perfusion from the left hemisphere to the right, and bring with them insight and healing.⁸¹ These are dopamine antagonists

(blockers): the left hemisphere relies more heavily on dopamine than does the right hemisphere.⁸² In schizophrenic patients, this balance of left over right dopaminergic activity is still more marked throughout the basal ganglia, though especially in the striatum, an important ‘powerhouse’ that is involved in co-ordinating many aspects of perception, motivation, motion and higher cognitive function.⁸³

Intellectual asymmetry, with a relative superiority of (typically LH) verbal skills over (typically RH) spatial skills, is commoner in schizophrenic subjects⁸⁴ and their relatives.⁸⁵

In schizophrenia, subjects tend to exhibit deficits typical of patients with right-brain damage. For example, they tend to neglect the left visual field.⁸⁶ On a line bisection task, which normally reveals dominance of the right hemisphere for visuo-spatial function, schizophrenic subjects perform like people with right hemisphere brain damage.⁸⁷ We have seen already (in Chapter 4) the extraordinary preponderance of right hemisphere strokes in the genesis of schizophrenia-like delusions in otherwise neurotypical subjects. In accordance with this, a small study showed that stimulating the right hemisphere, but not the left hemisphere, can cause temporary remission of delusions, and increase in insight (into the fact of being ill) in both manic and schizophrenic subjects.⁸⁸

Amazingly, there are published records of cases in which the delusions of a schizophrenic patient *disappear after a left hemisphere stroke*.⁸⁹ I am grateful to a colleague for bringing an additional, personal and hitherto unreported case to my notice. Her patient had a diagnosis of schizophrenia, and was bizarre, exhibiting delusional misidentification symptoms, thought block and auditory hallucinations, over many years. One day he presented complaining of slurred speech. ‘What struck me’, she writes, ‘was that for the first time ever he was interacting normally.’ There was no evidence of thought block or hallucinations, no delusions. He *engaged* with her for the first time. However, she wondered if he had had a left hemisphere stroke. She sent him for a scan, which revealed a left-sided pontine infarction. ‘For the next four months he continued to be his new character, and his schizophrenia was in remission.’ Sadly, however, as his left hemisphere recovered its function, his psychosis returned.

In summary, while there are undoubtedly abnormalities to be found in the structure and function of both right and left hemispheres in

schizophrenia, such evidence, for what it is worth, points sufficiently strongly towards right hemisphere deficits, resulting in exaggerated left hemisphere prepotency, to confirm the overwhelming phenomenological evidence. Let me put it like this: if, in the thankfully improbable circumstance that you wanted to take a 'normal' brain, and make its possessor behave like someone with schizophrenia, you would find yourself creating lesions mainly in the right hemisphere.

AUTISM AND RIGHT HEMISPHERE DEFICIT SYNDROMES: PHENOMENOLOGY

Readers who know people with some form of autism will recognise many parallels. The concept of 'autism', meaning a morbid self-absorption (from Greek *autos*, self) and a lack of contact with reality, is a core feature of schizophrenia.⁹⁰ The term was coined by Eugen Bleuler in 1908 to describe an aspect of schizophrenia, and was not applied in its current sense, to a developmental disorder first manifest in childhood, till Leo Kanner did so in 1943. Kanner thought that, while the conditions were obviously distinct and had a different chronology, there were 'remarkable similarities' with schizophrenia: some of those he noted were insularity, a desire for sameness, a deviance from normal pronoun use, a difficulty with understanding the intentions and viewpoint of others, a total lack of interest in people and an obsession with the inanimate.⁹¹ Kanner's classic paper, in which he first described the syndrome, noted as central to autism an

inability to experience wholes without full attention to the constituent parts. ... A situation, a performance, a sentence is not regarded as complete if it is not made up of exactly the same elements that were present at the time the child was first confronted with it.⁹²

Autism, like schizophrenia, is characterised by perceptual organisation deficits.⁹³ Indeed, one of the cardinal features common to schizophrenia, autism and right hemisphere dysfunction is the primacy of local over global attention.⁹⁴ There is in autism an inability to appreciate global information, or to integrate global, contextual information with local information, which is almost identical with that found in schizophrenia.⁹⁵ Kanner thought that the inability to experience wholes without full attention to the constituent parts was central to the condition.⁹⁶ The elements of insistence on sameness, an attention to parts of objects, a fascination with inanimate objects, and an uneven cognitive profile, may all be aspects of what has

been called ‘weak coherence’ – an over-emphasis on detail with respect to the whole.⁹⁷

Kanner also remarked on a fastidious refusal of food (interestingly parallels between autistic spectrum disorders and anorexia nervosa at many levels have been suggested more recently).⁹⁸ People with autism, who have difficulty with pronouns, and often refer to themselves, or to others in their presence, in the third person, show right hemisphere deficits in perspective-taking.⁹⁹ When neurotypical (normal) subjects hear or read a story, and take different perspectives, it is areas of the right hemisphere that underpin this; such right hemisphere functions appear to be impaired in autism.¹⁰⁰

As the reader will appreciate from earlier chapters, both autism and Asperger’s syndrome, which is part of the autism spectrum, have many features in common with right hemisphere dysfunction.¹⁰¹ Children that have neurological and neuropsychological right hemisphere deficits often display features of autism, such as solitariness, ‘oddness’, and difficulties in emotional expression and interpersonal relationships.¹⁰² Conversely, an overview of autism from a neuropsychological perspective emphasises that a host of features of autism are found in right, but not left, hemisphere deficit syndromes. These include abnormalities in:

gaze following, response to sound and deficits in attention,¹⁰³ showing of objects, responding and orienting to own name,¹⁰⁴ looking at other’s faces,¹⁰⁵ pretend play, proto-declarative pointing [pointing to draw the attention of another person to an object of interest in itself – ‘doggy!’ – by comparison with proto-imperative pointing, which is instrumental in demanding something – ‘biscuit!'] and gaze monitoring,¹⁰⁶ empathy and imitation,¹⁰⁷ joint-attention behaviour,¹⁰⁸ affect and personal relatedness,¹⁰⁹ self-awareness including self-recognition, self-other differentiation, body awareness, theory of mind, inter-subjectivity, ego/allocentrism, motion processing, language (pronoun reversal, inner speech, third-person perspective), self stability over time, autobiographical memory and narrative self ...¹¹⁰

Kanner also observed of autistic children that

they all come of highly intelligent families ... this much is certain, that there is a great deal of obsessiveness in the family background ... one other fact stands out prominently. In the whole group, there are very few really warmhearted fathers and mothers.¹¹¹

It is relevant that the important areas for mother-infant attachment, recognition of the mother's face and voice, and of self-other distinction are all in the right hemisphere, which is normally dominant in early childhood.¹¹² These areas are thought to be crucial for the development of a socially integrated human being. They are not functioning at the normal level in schizophrenia and autism.

Lyons & Fitzgerald conclude that their 'review of neural substrates underlying these processes has highlighted the significance of the right hemisphere ... right hemisphere impairment leads to a dysfunctional self-development in autism spectrum disorders.'¹¹³

And Allan Schore concludes that, while both hemispheres are 'affected by a common neuropathological process, at the core, autism represents a severe impairment of the right-lateralized cortical-subcortical implicit self system that acts unconsciously'.¹¹⁴

AUTISM AND RIGHT HEMISPHERE DEFICIT SYNDROMES: BRAIN CORRELATES

As mentioned, there appears to be a genetic overlap between schizophrenia and autism, each being over-represented in the lineage of the other. Abnormalities in right hemisphere structure and function are increasingly being reported in autism spectrum disorders (see note for details).¹¹⁵ Children with such disorders have reduced lateralisation. In neurotypical children, activity is ‘more integrative in the right and more specialized in the left hemisphere’: this well-characterised asymmetry is diminished in autistic spectrum subjects.¹¹⁶ In such subjects, social awkwardness¹¹⁷ and an inability to understand one’s own mental state¹¹⁸ are specifically associated with dysfunction in the right hemisphere (principally the temporoparietal region).¹¹⁹

There is reduction in white matter conductivity in autism.¹²⁰ Abnormalities in the extended white matter tracts of the right hemisphere have been implicated in the genesis of the condition: ‘the finding of microstructural abnormalities in the right inferior fronto-occipital fasciculus in autism spectrum disorders is exciting as it offers an insight into white matter abnormalities that may underpin a core deficit in the condition’.¹²¹

EEG studies in autistic spectrum disorders have also demonstrated largely right hemisphere deficits: a broad leftward asymmetry has been observed in subjects relative to normal subjects, especially in the temporal region, thought to reflect a failure of the right temporal region to generate EEG rhythms.¹²² Another study found a decrease in resting gamma power in the lateral leads over the right hemisphere.¹²³ Dysfunction primarily in right posterior regions has also been repeatedly observed.¹²⁴ Conversely, there is both abnormal functional connectivity and enhanced power in the left hemisphere.¹²⁵

In autism spectrum disorders there is a tendency for ‘over-connectivity in the local networks and under-connectivity in the long-distance networks.’¹²⁶ This is also one way of characterising respectively the left hemisphere’s neuronal architecture (shorter distance connexions) compared with that of the right (longer distance connexions).¹²⁷ It would go some

way to explaining the abnormal focus on detail at the expense of the big picture in such disorders (and schizophrenia).

Agenesis of the corpus callosum – absence of the corpus callosum from birth – occurs in at least 1 in 4,000 individuals, probably more, since many cases go undetected during life.¹²⁸ In general, individuals with the syndrome do not exhibit the same clinical picture as that found in split-brain patients, perhaps because during development the brain is plastic and undergoes reorganisation, allowing for the possibility of bilateral representations of language or visuo-spatial imagery;¹²⁹ and interhemispheric communication (although much slower) via other pathways such as the anterior commissure, and even via the cerebellum, may compensate.¹³⁰ However, intriguingly enough, many subjects with the condition do resemble individuals with *autism*.

Like those with autism, subjects with callosal agenesis exhibit deficits in language comprehension, especially in interpreting metaphor, humour, idiomatic phrases and proverbs, as well as tone of voice and body language. Many seem unable to get beyond literal interpretation, and to have difficulties understanding how meaning depends on context.¹³¹ Also like autistic (and schizophrenic) subjects, they have pronounced difficulty understanding social situations,¹³² difficulty imagining the social perspective of others,¹³³ a lack of self-awareness,¹³⁴ poor conversational skills¹³⁵ and problems verbalising emotional experience.¹³⁶ Like some, but by no means all, autistic individuals, they have been found to be slow at problem-solving, tend to have a low IQ and have associated difficulties in reasoning.¹³⁷ A recent comprehensive review of the area suggests that ‘congenital disruption of the corpus callosum constitutes a major risk factor for developing autism.’ The authors found that approximately a third of adults with agenesis of the corpus callosum showed the clinical diagnostic picture of an autism spectrum disorder.¹³⁸

If autism is common in callosal agenesis, abnormalities of the corpus callosum are common in autism.¹³⁹ Some studies have found only parts of it to be affected,¹⁴⁰ while others report reduced corpus callosum cross-sectional volume throughout the entire structure.¹⁴¹ However the salience of details, coupled to a difficulty in perceiving the whole, may be related not so much to reduced *interhemispheric* connectivity, as to reduced *intra*hemispheric connectivity, in autism – a further consequence of reduced

white matter volumes. Certainly, any alteration in the efficacy of the neuronal connexions carried by the corpus callosum will alter the hemisphere balance directly.^{[142](#)}

Impairment of the right hemisphere's capacity to inhibit the left hemisphere could result in functional interference likely to impinge particularly badly on the right hemisphere. From cases of early unilateral brain damage, epilepsy or hemispherectomy in childhood, where therefore one hemisphere then takes over the functions of both, we find that it is the typically right hemisphere aspects that tend to get squeezed out in favour of those of the left hemisphere, a phenomenon known as 'crowding' by language.^{[143](#)}

HEMISPHERES OR MODULES?

You may be thinking it odd that different conditions, with differing underlying pathologies, should eventuate in similar clinical pictures. But I suggest that that surprise stems from a misunderstanding of what we are dealing with.

The point is that though there may be a virtually infinite number of causes of a complex system's malfunctioning, there are only so many ways in which that malfunction can manifest itself. There are relatively few 'final common pathways'. To take a simple example, anything from a driver's turning up late, to a fuel leak, a suicide or a national strike (each of them in itself the result of any one of a myriad causes) will lead to the same result: your train is late. We are very much more complicated than the rail system, so there are more outcomes possible, but they are still drastically limited compared with the potential causes.

The brain is a series of nested neuronal complexes: nuclei and ganglia at one level, organisational foci, and broader functional regions within specific gyri or sulci (the folds of the cortex) at another, up to the level of one or other cerebral hemisphere as a whole. As I have noted, each hemisphere is capable of sustaining consciousness on its own, and each is one of the two most massively internally connected neuronal complexes on which we rely. If, at the very top of the pyramid of functioning of the human central nervous system, the product of all this organisation is the phenomenological world we inhabit (and which we also help to constitute), and if that product, as I suggest, requires balancing the contributions of the two hemispheres, an imbalance of some kind between the two will be a common element in mind/brain abnormalities. Which is not at all, of course, to say that all such abnormalities are the same, or that there will not also be tell-tale symptoms guiding us to a more specific diagnosis: there will be. But there should nonetheless be what Wittgenstein called 'family resemblances'.

Just stimulating a part of one hemisphere alters the overall balance between hemispheres. As Marcel Kinsbourne writes:

When use of a specialised part of a hemisphere is called for, it is activated by ascending pathways. This activation is not limited to

the specialised hemispheric area, but, presumably on account of the network characteristic of brain organisation, involves other parts of the hemisphere as well.¹⁴⁴

I have mentioned the stimulation of an entire hemisphere's function by administering ice water to the external auditory meatus of the contralateral hemisphere: caloric vestibular stimulation.

There is also a phenomenon, which the famous Swiss-Russian neuropathologist Constantin von Monakow termed 'diaschisis', a word which means 'distributed damage', and which has gone into the language of neurology.¹⁴⁵ It refers to the fact that damage to one area of the brain often results in much more widespread deficits, taking in areas that are only distantly, although functionally, connected with it. This concept has recently been revived, after neglect during a period of excessive focus on narrow localisation.¹⁴⁶

Two striking examples show why thinking at the hemisphere level is not only valid but of crucial importance.

In Chapter 4, I mentioned a systematic review of post-stroke psychosis.¹⁴⁷ The authors found that the regions affected were right frontal (30 patients), right temporal (26 patients) and right parietal (40 patients), as well as the right caudate nucleus (14 patients). That's quite a spread – only one region of the right hemisphere (occipital lobe) does not figure here as causing psychosis if damaged. (But it can.)¹⁴⁸

You might think that that is because psychosis is a rather broad concept. However, the same applies with a more circumscribed phenomenon such as appreciation of metaphor; research has implicated equally the right frontal and prefrontal cortex, right temporal, right parietal and right occipital regions. Again widespread hemispheric networks are responsible.

The overall point I am making here is that each hemisphere is profusely interconnected within itself, and that there is a tendency for apparently circumscribed lesions in different areas to give rise to similar manifestations, because interconnectivity means that the effects of a lesion are never functionally as localised as might be expected from the point of view of gross anatomy. Thus many different lesions may have similar, though rarely identical, ultimate consequences.

Overall, then, a pervasive over-localising tendency in brain research into schizophrenia and autism may lead one to miss real and important effects. Even relatively focal brain abnormalities tend to be reflected in hemisphere imbalance, and in the case of the long white matter tracts this will be still more likely to be the case.

Finally, one repeated clinical observation of mine offers perhaps some support both to the connexion between schizophrenia and right hemisphere dysfunction (as well as some cases of depression and left hemisphere dysfunction), and the idea that the dysfunction is widespread in the relevant hemisphere, rather than purely localised. This is the frequency with which psychotic patients refer to a subjective sense of hemisphere imbalance, almost as if they were able to diagnose their own condition. A beautiful example is provided by a patient of the contemporary phenomenologist Giovanni Stanghellini:

Twenty years ago. I heard a voice saying ‘You’ve got a hole!’ and the whole world deflated like a beachball ... Flattened, like a map – if it weren’t for the folds ... it was like a pinprick, something quite simple, here, on the right-hand side of my brain... ¹⁴⁹

Its richness lies partly in its reference to the ‘deflation’ of the right side of the brain; but it is also in the allusion to the sense in which the left hemisphere could be said to see not the world, but a map of the world, and to its related tendency to see the world flattened out – lacking in depth.

In psychotic subjects, those with schizophrenic delusions appear to intuit an imbalance. If the mind is functioning normally, with the right hemisphere as the Master, the working of the two hemispheres is experienced as integrated (according to the right hemisphere’s integrative character); if not, the division of, even antagonism between, these two modes of being is felt (according to the left hemisphere’s ‘either/or’ character). Cutting and Dunne report the cases of six schizophrenic patients who described simultaneous experience of two separate modes of thinking:

- ‘I began to be more aware of things– I was in two minds – I could snap out of it if I wanted’;

- ‘I was functioning on another level, one more in pictures, then another one – the abnormal one was the picture one’;
- ‘rational thinking was not right – there was my own personality and another one’;
- ‘mind working terribly, one was the natural working of my mind, me myself or me not myself boosting myself’;
- ‘parts of it were working, different wavelengths, two different wavelengths’;
- ‘my mind clicked into another sort of thing’.¹⁵⁰

Another patient reported that his ‘consciousness is not as whole as it should be ... I am *half* awake.’¹⁵¹ Still another that ‘the one speaking now is the *wrong ego* ... ’¹⁵²

Patients refer to ‘pressure over left side of head’, ‘things look odd in left visual field’, ‘thoughts positioned over left shoulder, connected to brain by strand’.¹⁵³ One schizophrenic patient reported that his ‘right side [was] empty’; another was ‘fogged up on left, nothing on right’. Interestingly, another complained that the ‘left side connects with the right side’; and still another that he got a right-sided headache when depressed and a left-sided one when ‘thoughts are positive’.¹⁵⁴ Other studies of schizophrenia contain similar reports of abnormal subjective lateralisation: ‘I have a feeling that my left and right forearms have switched places.’¹⁵⁵ (Notice not the arms, just the forearms, in accord with the characteristic part-orientation of the left hemisphere.)

Daniel Schreber, the subject of Freud’s only study of schizophrenia, describes in his memoirs a disruption of hemisphere relations: ‘In consequence of many flights of rays, etc, there has appeared in my skull a deep cleft or rent along the middle, which probably was not visible from outside but was from inside.’¹⁵⁶ Not dissimilarly, a woman described by Franz Gall in the 1830s insisted that

she perceived every thing differently with her left side from what she did with the right; that every thing affected her differently on different sides ... that sometimes her faculty of thinking was completely shackled on that side, and that this inability was accompanied by an icy torpor: it seems to me (these are her own

words, and she applied her hand perpendicularly upon the middle of her forehead) that from the front to the back of my head, the brain is divided into two distinct halves. 157

THE WORLD OF THE SCHIZOPHRENIC SUBJECT

A lot of things happen to the world in schizophrenia (and in autism): to the sense of the whole, of context, of the relation between mind and body; to the sense of connectedness to, and belonging in, the world; to one's relatedness to other human beings; to the sense of animacy; to what one might call the sense of naturalness, spontaneity and vitality; and to the very existence of the self.¹⁵⁸ Each of these aspects of experience is also compromised in right hemisphere damage; and problems with each of them are also recognisable, I believe, in the modern Western world, and have even become the focus of much of its literature and art in the last hundred years or so, as Louis Sass suggests.

I concur with Cutting that the Franco-Polish psychiatrist and philosopher Eugène Minkowski provides 'the most comprehensive psychological account of schizophrenia ever written'; and that 'his observations are so accurate and profound' that they anticipate and bear out not only current neuropsychological models of schizophrenia, but confirm contemporary neuropsychological theories of the functioning of the mind and brain in its normal state.¹⁵⁹ RD Laing called Minkowski's work 'the first serious attempt in psychiatry to reconstruct the other person's lived experience', and I would add that it is still the most important attempt ever made.¹⁶⁰

Minkowski immediately recognised the importance of abnormalities in the experience of time in schizophrenia, an important theme of the philosopher Henri Bergson, which I will come to in Chapter 22; both this and another foundational aspect of Bergson's thinking, the distinction, which he arrived at by introspection, between what we now know to be the left hemisphere's take (which he called *intellect*) and the right hemisphere's take (which he called *intuition*). When Minkowski applied the difference between *intellect* and *intuition* to the world of schizophrenia, he discovered in effect that for the schizophrenic subject Bergson's *intuition* becomes atrophied, and Bergson's *intellect* becomes hypertrophied (exaggerated). And he gives these antithetical pairings (which could stand for right versus left hemisphere) as characteristic of schizophrenia: ¹⁶¹

ATROPHIED	HYPERTROPHIED
<i>life</i>	<i>map</i>
<i>instinct</i>	<i>brain</i>
<i>feeling</i>	<i>thought</i>
<i>'faculty of penetration which synthesises'</i>	<i>'analysis of infinite details'</i>
<i>trust in impressions</i>	<i>demand for proof</i>
<i>movement</i>	<i>immobility</i>
<i>events and persons</i>	<i>objects</i>
<i>presence</i>	<i>representation</i>
<i>goal</i>	<i>preliminaries</i>
<i>time</i>	<i>space</i>
<i>flow</i>	<i>measure</i>

I believe, to varying degrees, this shift has become characteristic of the way we live now. In fact if you look at the list on the left, it characterises embodied vitality; on the right, it characterises the dead hand of mechanism, scientism and bureaucracy, under the shadow of which all our lives are now 'lived'. The Swiss psychopathologist Roland Kuhn saw, at the core of psychosis, 'an inauthentic materialisation, technicalisation and mechanisation of everything'.¹⁶² That suggests there is an imbalance verging on mental illness in our current society, since these are some of its most prominent characteristics.

In what follows I will examine some abnormal aspects of the phenomenological world in schizophrenia, shared by the right hemisphere-damaged subject, and indicative, though in an extreme form, of some of the characteristic tendencies of the contemporary world.

Things fall apart

Given the centrality of deficits in attention to the whole in schizophrenia, autism and right hemisphere damage, let's begin by looking at what happens to our capacity to understand the world when fragmented attention is all we have to go on.

In a word, there is deluge. Temple Grandin, who has written illuminatingly about her autism, describes how her 'mind works similar to an Internet search engine', and how for a long time, in 'everything in life, I was overwhelmed with a mass of details'.¹⁶³ Minkowski reports one of his

schizophrenic patients as telling him that ‘whoever speaks of a clock speaks of the hands, cogs, springs, case, pendulum, etc ... His mind ... decomposed every object that it met.’ ¹⁶⁴ Detail triumphs at the expense of the whole: ‘I am overwhelmed by too much detail’, records one schizophrenic subject, ‘too much detail in objects’. ¹⁶⁵ Remember that in autism any situation, any sentence, is not regarded as complete if it is not made up of *exactly the same* elements that were present at the time the individual first encountered it. ¹⁶⁶ The sense of the whole is lost.

Elyn Saks gives a vivid report of her own experience during a psychotic episode:

Consciousness gradually loses its coherence. One’s centre gives way. The centre cannot hold ... No core holds things together, providing the lens through which to see the world, to make judgments and comprehend risk. Random moments of time follow one another. Sights, sounds, thoughts, and feelings don’t go together. No organizing principle takes successive moments in time and puts them together in a coherent way from which sense can be made. ¹⁶⁷

As a result of the loss of integrative imagination, there is no proper hierarchy of attention: there is no way of constructing a coherent picture in which irrelevancies can be detected and excluded. Instead every detail stands out as equally important, demanding attention in its own right, and the result is an overload of distracting fragments. Here is the report of a schizophrenic patient:

Everything seems to grip my attention although I’m not particularly interested in anything. I am speaking to you just now but I can hear noises going on next door and in the corridor. I find it difficult to shut them out and it makes it more difficult for me to concentrate on what I’m saying to you. Often the silliest little things that are going on seem to interest me. That’s not even true; they don’t interest me but I find myself attending to them and wasting a lot of time this way. I know that sounds like laziness, but it’s not really. ¹⁶⁸

This again seems to describe an aspect of the modern, information-soused, overstimulated, condition. As in modern life, there is no hierarchy of importance, but a democracy of the importunate. A different patient says:

I was surrounded by a multitude of meaningless details ... I did not see things as a whole. I only saw fragments: a few people, a dairy, a dreary house ... They did not stand together in overall context ... My impressions did not flow as they normally do. If I had not continuously reminded myself of where I was going, I would just as gladly have stood still somewhere.¹⁶⁹

Losing any sense of the whole is bound up closely with two other phenomena: the living flow of time, of seamless experience, is lost; and, cut off from vitality, intuition, emotion and the body, it becomes static and abstract, as if only conscious mental effort can recompose it once more. Of one patient, the psychiatrist Françoise Minkowska writes:

All his activity is governed by the idea of a strategy which inevitably applies only to immovable objects: our patient has no grasp of the whole, he sees only isolated parts and gets nowhere. In developing his plan, he relies purely on his powers of cerebration, since *instinct*, as he says, *has gone missing*. Speaking of music one day, he declares that for him it is no more than a succession of sounds: '*I don't know how to feel – everything has to go through my brain.*'¹⁷⁰

The sense of direction, purpose and overarching meaning, necessary for inhabiting time and experiencing music, are lost. Another patient reported: 'I may look at the garden, but I don't see it as I normally do. I can only concentrate on details. For instance I can lose myself in looking at a bird on a branch, but then I don't see anything else.'¹⁷¹ Yet another 'could not look at the whole door ... She could only see the knob or the keyhole or some corner of the door. The wall too had to be fragmented into parts.'¹⁷²

This has the effect of breaking up the whole experienced world, with particularly damaging effects on the *living* world: loss of the seamless flow of experience. 'Everything I see is split up', complained another patient:

it's like a photograph that's torn in bits and put together again. If somebody moves or speaks, everything I see disappears quickly and I have to put it together again.¹⁷³

There is, then, a need for effortful *recomposition* to make the whole comprehensible. Meaning which comes from perceiving the whole has to be effortfully recaptured (if it can be at all) by adding pieces of information together. This too seems to me part of the modern predicament. In the words of patients themselves:

- It's like eating a soup where you taste the individual ingredients: you taste the flavour of the soup itself only after *reconstructing* it.¹⁷⁴
- I have to put things together in my head. If I look at my watch I see the watch, watchstrap, face, hands and so on, then I have got to *put them together* to get it into one piece.¹⁷⁵
- I can concentrate quite well in [*sic*] what people are saying if they talk simply. It's when they go on into long sentences that I lose the meanings. It just becomes a lot of words that I would need to *string together* to make sense.¹⁷⁶
- It's the same with listening. You only hear snatches of conversation and you can't *fit them together*.¹⁷⁷

Time slows or disappears once it is represented as 'fractured':

Time has disappeared. Not that is longer or shorter, it's just not there; you could say there are bits of time, small pieces, *shaken and mingled*, or you could say there is no time at all.¹⁷⁸

The phenomenon of fragmentation affects everything. It probably results from at least three related deficits in schizophrenia, which are also deficits in the modern world-picture: loss of global or *Gestalt* perception, as we have seen; deficits in contextual understanding; and difficulty discriminating familiar from strange stimuli (all right hemisphere-related deficits).¹⁷⁹ Fragmentation renders things uncanny, alien – including the

embodied self. ‘I feel my body breaking up into bits’, says one schizophrenic subject.¹⁸⁰ Remember that knowledge of the body as parts, rather than as a whole, is dependent on the left parietal region – which is here acting without the countervailing sense of the whole, the body schema, provided by the right parietal region.

Alienation from the body

Fragmentation affects the union of mind and body, body and soul. Schizophrenia could be seen as ‘involving extreme disembodiment, a sense of radical separation from one’s own being as a physical entity’.¹⁸¹ One patient says,

I feel distant from myself ... It’s as if the body were there by itself, without being co-ordinated with anything else... I have this feeling of un-harmony, of a separation from my inside, which is where I feel the vital force flowing ... Sometimes it’s as if I weren’t the one who’s thinking... The body is something that functions, not something that’s mine that I live ... I live my life in the third person.¹⁸²

We will come to loss of vitality and the third-person perspective in due course. Another patient reports the body as emptied out like a husk: there is ‘no inside of the body, but only a frame’. He says that when he eats ‘the food is falling in a vacuum ... Behind the chest is nothing, only a big hole.’¹⁸³ One of Bleuler’s patients exclaimed, ‘Body and soul don’t belong together; there’s no unity’.¹⁸⁴ What seems to be happening here is a diminishment, evisceration and alienation of the body in relation to the mind: the birth of Cartesian dualism, of which we are all the heirs. I will have more to say about this in Chapter 22, the chapter on the subject of time.

A tendency towards analysis is another cause of loss of the sense of the whole. The fact that fragmentation plays such a part in schizophrenia is philosophically significant: fragmentation is the drive behind an atomistic vision of the world, abstraction and disembodiment, and an untempered belief in analysis. As a patient of Sass’s put it: ‘Well, look at the word

analysis. That means to break apart. When it turns in upon itself, the mind would rip itself apart.’¹⁸⁵ The schizophrenic mind, in seeing everything, as the left hemisphere does, as a ‘show’ or representation is inevitably turned back on its own creations, working on itself, being denied access to the freshness of experience mediated intuitively by the body and its sensations. And patients with schizophrenia become excessively analytic in their approach to life, as we will see. It is a striking fact that the same self-referential, disembodied, non-intuitively grounded, representational world, the consequence of right hemisphere failure, is also the outcome of years of practised speculation by some analytical philosophers, as Paul Feyerabend reflected.¹⁸⁶

Loss of self

The effect of fragmentation and alienation from the body is to erode one’s identity. Sometimes the belief arises that one simply *is* ‘someone else’ – an extraordinary concept given that, however changed one might feel, it seems intuitively obvious that one can only be who one *is*, not someone else. ‘I am somehow strange to myself – I am not myself’, says Wolfgang Blankenburg’s schizophrenic patient, Anne.¹⁸⁷ Another says: ‘I am not able to feel myself at all.’¹⁸⁸ This is because the subject no longer has a self: in its place, a disembodied eye clinically inspecting the shell where the self should be.

Without a self, there is no capacity for intersubjectivity, for the experience of shared time in a shared world, and this is closely linked with the ‘freezing’ of reality, as we will see.¹⁸⁹ As Merleau-Ponty noted, ‘presence’ concerns *both* self *and* world: subject and object are just two abstract ‘moments’ within a unique structure – *presence*.¹⁹⁰ Sass comments:

‘Presence’ is so very general, and so very taken for granted, as to make any description sound empty or tautologous. Yet this dimension is of crucial importance in human existence; its absence or attenuation shows up in derealisation and depersonalisation experiences of various kinds, involving subjectivism and solipsism as well as deadening objectification. ¹⁹¹

Both subjectivism and solipsism, on the one hand, and morbid objectification on the other – but I will come to that – are equally found in schizophrenia: each is a breakdown of betweenness. ‘Self and other’, as distinct but not isolated, then, is a necessary dipole, necessary for there to be relation; and it is one that is collapsed in schizophrenia. Loss of self may be experienced in a number of ways: as loss of boundaries between the self and other; as the self breaking apart; as alteration in the form of the face or body; in a lack of the sense of ownership of the body and of its actions; as well as in an alienation of the self from empathic connexion with the world and with others, from which in normal circumstances the self draws its life. We are experiencing a rise in so-called dissociative disorders, such as borderline personality disorder, conditions in which the sense of one’s own identity is weakened or lost altogether. In the modern world the individual may experience himself or herself as no longer having a role and a place in a close-knit community on a human scale, and therefore as engulfed in the mass – of the populace, of the city, of bureaucratic organisations and global corporations – relatively powerless. No wonder people emphasise (with tragic and damaging results) something called ‘identity’, in which, ironically, their true identity is swallowed up.

In such a condition, there is no traction between self and world, or between self and other selves. Bin Kimura calls schizophrenia a disturbance of *das Zwischensein* (literally, ‘the being-between’).¹⁹² English lacks a term for it: it is what I have called ‘betweenness’. In schizophrenia, because of the lack of betweenness (without which the world is incomprehensible), boundaries are experienced where none should be, and where boundaries should be, none is experienced. These are two facets of the same thing: a loss of identity. In modernism, too, that sense of the self which can only come about when we are still embedded in the context of a shared world becomes eroded.

Eugen Bleuler, at the dawn of modern psychiatry, thought a defining feature of schizophrenia is that ‘the person loses his boundaries in time and space’.¹⁹³ For sufferers, boundaries sometimes liquefy in a terrifying meltdown of identity. The pieces of the world that should be shared – for example, emotions – are not, and those that should be private – for example, physical intimacies – are shared. The body is fused with others, and vulnerable, while the psyche is invulnerable and isolated. John Cutting

writes that what he has called ‘violability’ occurs in no less than one-third of schizophrenics:

- own eyes embedded in paper as he reads;
- friend’s body erupting through his body;
- others’ faces feed into him;
- other people’s bodies intermingle with hers. [194](#)

The Austrian psychiatrist, Paul Schilder, a pupil of Freud, reported a patient who felt that

when I am melting I have no hands. I go into a doorway in order not to be trampled on. Everything is flying away from me. In the doorway I can gather together the pieces of my body. It is as if something is thrown in me, bursts me asunder. Why do I divide myself in different pieces? I feel that I am without poise, that my personality is melting and that my ego disappears and that I do not exist anymore. Everything pulls me apart ... the skin is the only possible means of keeping the different pieces together. There is no connexion between the different parts of my body. [195](#)

And in James Chapman’s important 1966 paper on the phenomenology of schizophrenia, we find two patients:

When I look at somebody my own personality is in danger. I am undergoing a transformation and myself is beginning to disappear ...

I feel my body breaking up into bits. I get all mixed up so that I don’t know myself. I feel like more than one person when this happens. I’m falling apart into bits ... [196](#)

In schizophrenia the results are terrifying and extreme, but they can be seen as vivid metaphors of a disintegration of the boundaries between the private and public, between the embodied sense of the whole that must be

intuitively understood and the graphically explicit snapshots of fact and image in our contemporary world, in which there is an erosion of empathic connexion coupled with a promiscuous divulging, a devaluing of the personal. The confusion of identity is associated with the absence of two things, exemplified in these vignettes: permanence from moment to moment in *time*, and integration of parts in *space*. When there is no self, there can be no other; and when there is no other, there can be no self. What in the past gave us that stable ‘other’ was our culture, stretching in time back in the past and forwards into the future as part of a living tradition; ramifying laterally into kin and community, and the land out of which we came and in which we live. But once ‘anything goes’, nothing goes. There is no purchase between the individual and the world.

One patient complained that ‘increasingly I began to feel that I sort of fused with my surroundings’. ¹⁹⁷ Though there are elements in schizophrenic discourse that sometimes sound like a perhaps desired state of spiritual awakening, we should clearly distinguish them from more authentic-seeming moments of spiritual enlightenment. The quality of distress alone that is associated with them is indicative: spiritual enlightenment is invariably described in terms of a deep serenity. What they do illuminate, though, is precisely how important an intact sense of self is to the genuine experience of self-*transcendence*.¹⁹⁸

Both ‘the sense of an integrated self and the differentiation between the self and world’ depend on the integrity of the right temporoparietal region.¹⁹⁹ Activation of the right somatosensory cortex is associated with ‘a preservation of the sense of self’.²⁰⁰ The link between pathologies of the self and right hemisphere damage is striking. In John Cutting’s series of such phenomena following unilateral brain damage, he found breakdown of boundaries between self and other, just as in schizophrenia, in 11 cases: all 11 involved right-sided damage only. He also recorded a willingness to disown responsibility for one’s own actions or thoughts, which he calls ‘causal repudiation’: eight out of the nine cases were attributable to right hemisphere damage.²⁰¹ Such disowning of responsibility is another common finding in schizophrenia, and some would say in the ‘culture’ around us.²⁰²

Devitalisation

A patient of Minkowski's speaks (the italics are added to draw attention to changes that have obvious hemispheric implications):

Everything around me is *immobile*. Things present themselves in *isolation*, each on its own, *without evoking any response* in me. Certain things which should produce a *memory*, evoke a host of thoughts, present a *picture*, instead remain isolated. They are *understood rather than experienced*. It is as if a *pantomime* is being played out around me, one in which I cannot take part – I remain on the *outside* of it. My critical faculty remains, but I *lack any instinctive feel* for life. I can no longer manage to give enough *life* to anything I do. I can no longer shift between major and minor key, and yet no life is supposed to be spent in a single tonality. I've lost contact with all sorts of things. Any notion of the *value and complexity* of things has disappeared. There's *no flow* between me and the world: I can't abandon myself to it. All around me is completely and utterly *fixed*. I have even less room to manoeuvre with respect to the future than I have with the present or past. There is, inside me, a sort of *routine* which makes me quite incapable of imagining the future. The *creative power is abolished* in me. I see the future as a *repetition* of the past.²⁰³

Here are a host of interrelated points, which describe the plight of modern humanity as exemplified in the writings of modernism. Not only is there immobility, but things are fragmented, 'presenting themselves' in a disconnected way, each on its own: no betweenness. What's more, there is more specifically no flow 'between' things: between her and the world, where things 'evoke' no emotional response, where she can no longer 'abandon' herself to the world, a world she cannot join, and where she must remain 'outside'. Life becomes unreal, seeming like a 'pantomime'. It is routine and repetitive, always the same. All creativity is gone. Life is no longer experienced, which is the only way in which it can truly be understood (right hemisphere fashion), but 'understood', which is to say reduced to a conceptual object, a re-presentation (left hemisphere fashion) outside of time.

The sense of authenticity, of reality, is, or used to be, taken for granted by most of us – for that, too, is a casualty of our age: remember Minkowska

(and Minkowski) noting the ‘demand for proof’ in schizophrenia? That’s where we live now. When it is lost, sufferers describe a ‘sense of separation, unreality, or deadening’, which is ‘inherent in a stance or attitude of disengagement’;²⁰⁴ ‘a mental remoteness’ in the words of one patient.²⁰⁵

The natural givenness of experience makes what we call reality possible at all. Without it we become no longer the subject of experience, in the normal sense, but its object, experiencing our *experience*, as if at second-hand: confronting a re-presentation, no longer inhabiting a presence. The schizophrenic mind, like the left hemisphere, flattens reality into one single plane, placing the observing eye and what it observes on the same level: parallel phenomena within the world, rather than inseparable facets of the single experience of a living subject.

Daniel Schreber seemed to see within him a second mind’s eye, engaged in the act of contemplating his own consciousness or thoughts (a phenomenon commonly depicted in the paintings of schizophrenic subjects).²⁰⁶ For him, the once intuitively understood was forced out of its context and could be accessed at one remove only, and therefore rationalistically: in other words, completely *mis*-understood. ‘What happens in these experiences’, writes Sass, ‘is that the tacit becomes focal: there is a rendering explicit of the implicit, of what would normally lie unnoticed in the back-ground of experience.’²⁰⁷ And what should be intuitive becomes a matter of calculation.

The lived self is highly dependent on the right hemisphere: the first person perspective depends on the right parietal lobe.²⁰⁸ The objectified self is still supported by the left hemisphere, so it may be that the schizophrenic subject recognises that a form of self persists, but that he or she no longer *inhabits* it. A patient with schizophrenia says ‘my first personal life is lost and replaced by a third-person perspective’; he further explains that he constantly witnesses his own experiencing, at one remove.²⁰⁹

We met the third-person perspective in schizophrenia before. A common feature of auditory hallucinations in schizophrenia is that voices speak *about*, not *to*, the self, using the third person: not ‘you are just a machine’, but, discussing among themselves, ‘he is just a machine’. Schizoid and schizophrenic persons tend to drop the first person in favour of a more impersonal language (‘the thought occurred that’) – similar to the way we are taught to write scientific reports – and, according to Bleuler, ‘schizophrenics can write whole autobiographies without manifesting the

least bit of emotion. They will discuss their sufferings and their actions as if it were a theme in physics.’²¹⁰ When a patient of Minkowski’s was asked to write about his life ‘characteristically, he only mentioned objects, walls, boxes, bolts, and bolt-holes; not one living person entered his description. One would say that his whole life was made up of solid and immovable objects.’²¹¹

Disengagement makes us objectify what we see, including ourselves and our own bodies. As Cutting puts it, following a distinction made by Sartre and Merleau-Ponty, the body ‘is both *en-soi* – a thing-like object to me when I look at it when *still*, and to you when you look at me when *still* – but also *pour-soi*, my agent when I use it for me, and for you when you see me *carry out an action*.’²¹² The tendency to stasis denatures, and renders inanimate: thus in both right hemisphere damage and schizophrenia, the body is an object in the world alongside other objects, not the very medium of experiencing the world.²¹³ Human beings, their minds, their brains, their bodies and the world, all become *things* in schizophrenia. So, write Stanghellini and colleagues,

there is an increased degree of ‘thingness’ in the body. Parts of oneself are spatialised, as if they were not part of the living body. Also, the body is experienced as devoid of life or substituted by some kind of mechanism. A typical sentence is: ‘She felt programmed like a robot’ ... In general, the body or its parts are experienced as mere thing-like entities, rather than as living flesh ... as if they were dis-integrated from the living totality of one’s body.’²¹⁴

These things or objects are, however, not specific and concrete, but general and abstract. They are no longer unique, but representatives of a class. Classes, categories take over from real people and real things. For one of Minkowska’s patients, objects merged and seemed alike – similarity became the one and only point of view under which they could be regarded. Their individual nature had been wiped out.²¹⁵ Minkowski reports another patient for whom people were no longer seen as individuals but only ‘schematic mannequins’.²¹⁶

This is the bureaucratic perspective: abstract, grossly simplified, dealing in categories, reducing life to puppetry. And it is often expressed using nouns in preference to verbs, and abstract nouns in preference to concrete ones.

The talk of schizophrenic subjects tends to have an excessively abstract, excessively general, quality (which is aptly known to psychiatrists as ‘pseudo-philosophical’).²¹⁷ Beyond that, they tend to use language that lays emphasis on the static aspects of experience at the expense of the dynamic and emotional, thereby evoking a universe more dominated by objects than by processes or actions. This natural inclination to immobility is embedded in schizophrenic speech, which is characterised by an excess of adjectives (thing-describers) and a dearth of adverbs (process-describers).²¹⁸ And to the extent that schizophrenics use adverbs they tend to prefer spatial adverbs to temporal ones (for example, ‘where’ may replace ‘when’).²¹⁹

Incidentally, aspects of such a linguistic shift can be seen in the poetry of Friedrich Hölderlin, who developed schizophrenia in his middle years. After the onset of his illness he cut out the word ‘I’; and, according to his editor Friedrich Beißner, ‘never depicts a unique instance in its particularity, but only ever sees the *type*’. He cleaved to an eternal present, in which all became generalised.²²⁰ His language came to incorporate an abundance of purely conceptual abstract nouns hitherto unknown in his poetry, such as ‘view’, ‘sublimity’, ‘apparition’, ‘spirituality’, ‘friendliness’, ‘inwardness’, ‘humanity’, ‘pastness’, and ‘familiarity’.²²¹

As Sass observes, ‘we typically find that, while schizophrenics sometimes manifest seemingly literal or concretistic thinking, they are also given to unusually *abstract* modes of cognition’.²²² That may seem odd, but let me explain.

In acute schizophrenic discourse, there is a tendency for responses to lose ‘connection to their referent’, and become lost in ‘a bewildering variety of *intraverbal* associations’.²²³ (This is reminiscent of modern money markets in which money displaces the lived reality which alone gives it meaning, and appears to take on a ‘life’ of its own, undergoing a myriad transactions with itself.) As the referential links to the situation become obviously less and less adequate, the productions do not show signs of halting, but instead are redoubled.²²⁴ (In right hemisphere damage there is often logorrhoea – a meaningless hypertrophy of language.)²²⁵ Searching

for what accounts for the strangeness of schizophrenia, Freud noted that ‘we eventually come to realise that it is the predominance of what has to do with words over what has to do with things.’²²⁶

Freud’s use of the word ‘things’ there may seem to contradict what I have just been at pains to explain about ‘thingness’ in schizophrenia. Unfortunately, in English we do not distinguish between two almost opposite senses of the word ‘thing’: (1) an inanimate object (*Gegenstand*) by contrast with a living entity; and (2) a thing as an object or matter of concern to one, tangible or intangible (*Sache*) – one’s ‘stuff’, if you like – by contrast with a purely abstract concept. Freud’s word for ‘what has to do with things’ here is *Sachbeziehung*, his point being that schizophrenics prefer abstractions to the life those abstractions represent.²²⁷ Indeed, excessive abstraction has been described as ‘probably at the source of cognitive deficit in schizophrenia’²²⁸ – living in the map, not the world: words that refer only to other words; abstractions that become more real than actualities; symbols that usurp the power of what they symbolise: the triumph of theory over embodied experience. I believe there are resonances here with academic trends in the humanities, with scientism, and even with the world-picture of the average Western citizen.

The common factor in these is an aversion to life; we come to prefer either inanimate objects or words – both left hemisphere predilections. As Cutting formulates it, ‘the schizophrenic self is concerned with universal essences, not particular things or persons ... with names and signs, signifiers detached from what they signify, and ... talks like a philosopher’. (Arthur Tatossian thought the cast of mind exhibited by Husserl in *Ideas I* ‘indistinguishable from the schizophrenic’s actual *modus vivendi*’.)²²⁹ Interestingly, Freud himself commented more than once on the relationship between schizophrenic thought and a tendency in philosophy – ‘a paranoid delusion [is] a caricature of a philosophic system’²³⁰ – a point worth noting, as I shall return to the topic in Part II:

When we think in abstractions there is a danger that we may neglect the relations of words to unconscious thing-presentations, and it must be confessed that the expression and content of our philosophizing then begins to acquire an unwelcome resemblance to the mode of operation of schizophrenics. We may, on the other hand,

attempt a characterisation of the schizophrenic's mode of thought by saying that he treats concrete things as though they were abstract.²³¹

If your world disintegrates, you stop seeing anything in context, and it becomes puzzling, even frightening. Its sheer facticity then stands out, since it can no longer take its place in any world schema of other things and people that would give it meaning. Renée, a highly articulate young woman with schizophrenia, describes how when, for example, she looked at a chair or a jug, she no longer saw it as situated in the world as something to sit on or something to hold liquid, but standing forth as under a spotlight:

things looked smooth as metal, so cut off, so detached from each other, so illuminated and tense that they filled me with terror ... In the silence and immensity, each object was cut off by a knife, detached in the emptiness, in the boundlessness, spaced off from other things.²³²

It is no longer *eine Sache*, but become essentially *ein Gegenstand*. In Heidegger's terms, these familiar objects are no longer *zuhanden*, embedded in the world and implicit, but stand forth as *vorhanden*, isolated and explicit, a consequence of the left hemisphere's focussed self-conscious attention, whose harsh spotlight denatures what it 'illuminates'. Her description makes them sound as if they formed part of a de Chirico painting. Or were Platonic forms.

Tatossian described hallucinations as aperspectival, complete and essential – in the Platonic sense – not like normal perception, which is necessarily incomplete and particular. And he links this with the absence of a real perceiving subject: 'in its *essence*' (and the emphasis is his)

perception is incomplete: for that reason, it is an action, an effort, even if that effort is not 'felt' psychologically; and this implies ... the perceiving subject.²³³

Since such a subject no longer exists for the schizophrenic, his view becomes a view from nowhere.²³⁴ 'Madness', wrote Roland Kuhn, '... fails in the attempt to achieve a finite, a truly temporal, perspective on one's

existence.’²³⁵ Sass comments that in schizophrenia there is ‘the sheer sense that this event is in certain respects a copy of some prototype ... like some Platonic or noumenal essence, lying behind the merely phenomenal world one directly experiences’.²³⁶ As Cutting says, the patient talks like a philosopher (or some philosophers talk like patients): both draw excessively on the left hemisphere mode of being in the world.

Concrete instances are always unique; only an abstraction can be general. The abstractions, for which the left hemisphere has an affinity, are derived from the unique incarnate cases taken in by the right hemisphere, and are therefore *secondary* to them. Yet from the left hemisphere’s own viewpoint, not having insight into what the right hemisphere knows, the situation appears reversed, and abstractions come to appear, in Platonic fashion, *more real than the real-world instances from which they are derived*. Thus the dramatist Antonin Artaud, who suffered from schizophrenia, remarked: ‘I go from the abstract to the concrete and not from the concrete toward the abstract.’²³⁷

Effectively the schizophrenic subject becomes like the scientist: no longer intuitively inhabiting a body and an embodied world, as it were from the inside, but inspecting it, as if an alien *thing*, from the outside. As Cutting writes:

If human experience is rated on an axis of ‘thingness’ at one end and ‘myiness’ at the other, then schizophrenics fall beyond normal subjects at the ‘thingness’ end and depressives fall beyond normal subjects at the ‘myiness’ end.²³⁸

A schizophrenic patient says ‘it is as if I am an outsider’.²³⁹ Objectification is reciprocally related to a sense of alienation from the world at large: objectifying alienates, alienation objectifies. Observing one’s life, as a scientist might, from the outside, causes reality to change utterly. The body *pour soi* is replaced by the body *en soi*: *der Leib*, the lived body – the body one *is* – gets replaced by a deanimated anatomical entity, *der Körper*, the corpse, the body one *has*.²⁴⁰ These tendencies lead us to live in a world in which abstractions are more real than whatever it is they represent, in which the individual being is swallowed up in a category, in which words become more important than acts or facts, and in which the

living is turned into something inanimate. Reader, do you recognise this world?

‘Once I was a man’, said one patient, ‘with a soul and a living body [*Leib*]’,

and now I am no more than a being [*Wesen*] ... Now there is nothing left but a corpse [*Körper*] and the soul is dead ... I hear and see, but I know nothing any more, for me life is now a problem ... I live on now in *eternity* ... the branches on the trees sway, other people come and go in the room, but for me *time no longer flows* ... Thought has changed, there’s no more style ... What is the future? It can’t be reached ... All is a question mark ... Everything is so *monotonous*, morning, noon, evening, past, present, future. Everything *keeps starting all over again*.’²⁴¹

Whitehead saw that ‘there is no such thing as life “at one instant”’.²⁴² Substitution of instants for the vital flow causes life to drain away. Minkowski called this ‘loss of vital contact with reality’, and associated it with the loss of the sense of flow.²⁴³ For the normal person, he maintained, the world is not just an assemblage of external stimuli, atoms, forces and energy, but ‘*a moving stream which envelops us at all points* and constitutes the milieu without which we would not know how to live.’²⁴⁴ ‘All of this’, he wrote,

leads one to surmise, at the very least, that this vital contact with reality is bound up with the secret dynamic force of our life. The rigid concepts of our spatial thought can’t get near it. Metaphors are far more to the point here than definitions. Only they can impart some clarity to the notion of vital contact with reality.²⁴⁵

The schizophrenic subject, for whom this is lost, is ‘attacked in his vital dynamism’: he ‘can only *juxtapose*.’ His thoughts are ‘immobile as statues’. Travelling by train, he will complain that the world goes past too fast for him to find the static moments with which to ‘solder together mentally the infinite number of points’ into which thought had sundered movement.²⁴⁶

This is an exact expression of the way the left hemisphere has mechanically to reconstruct what in the right hemisphere is a living and indivisible flow. It is an attempt in vain to breathe life into a corpse.

As schizophrenic patients exhibit emotional indifference, passivity and inertia, so do right hemisphere-damaged patients.²⁴⁷ We have seen that the left hemisphere has an affinity for the inanimate, and that in right hemisphere damage, body parts on the left may become exaggeratedly thing-like: it is hard to forget the patient of Ehrenwald's, for whom the left side of the body was replaced by a contraption of planks and shelving.

Similarly, in schizophrenia, a patient may complain of 'a feeling that his own existence was as of a dispensable object, as if he was a thing, a refrigerator, and not a human subject.'²⁴⁸ Cutting quotes examples of subjects saying they have a machine in their ear, pieces of metal in their legs, or a bag of petrol in their body. Tatossian described in detail the case of a patient, Hélène Jacob, almost unsurpassed for its detail, and I will draw on it later in the chapter: when Hélène speaks of trying to mend herself, the word she uses is not *se guérir*, to heal, but *se reconstruire*, to reconstruct herself. She was just a few steps ahead of us, we who are taught that we are just machines; that the lights are on, but no-one is at home.

I mentioned that it has been my clinical observation over the years that schizophrenics are far more likely than other patients to refer to their 'brain'. The mind, a process in time, becomes the brain; but the brain, too, is no longer processual – rather it is seen as a hollow thing, containing other things. 'My brain has become a sort of box for thoughts', comments one schizophrenic patient.²⁴⁹ Human beings – their minds, their brains, their bodies and the world – all become *things* in schizophrenia. One schizophrenic patient pronounces: 'people should take inanimate matter as a model in order to constitute their firmness and the rationality of their movements.'²⁵⁰

Bergson thought that what he called 'intuition' (RH) was modelled along the same lines as life itself; what he called 'intelligence' (LH), on the other hand, was characterised by a complete lack of understanding of life. Similarly, 'right-hemisphere-damaged subjects tend to experience a lack of life-like qualities', writes Cutting, 'whereas left-hemisphere-damaged subjects experience the exact opposite.'²⁵¹ (We have already seen this vividly demonstrated in Chapter 2.) A Swiss writer, Robert Walser, who later developed schizophrenia, thought that Cézanne must have

looked upon his wife as if she were a fruit on the tablecloth. For him the outlines, the contours of his wife were exactly the same simple but also complicated ones as he'll have seen around flowers, glasses, dishes, knives, forks, tablecloths, fruits, and coffeepots and cups.²⁵²

True self-transcendence makes one come alive; but the loss of self that is consequent on the failure of integration across time makes subjects with schizophrenia see themselves as devitalised or dead. Minkowski's insight into the core of schizophrenia was that it is a 'loss of vital contact with reality'.²⁵³ A patient of Bleuler's was 'dead and yet living'.²⁵⁴ Here are a number of patients of Jaspers:

I am only an automaton, a machine; it is not I who senses, speaks, eats, suffers, sleeps; I exist no longer; I do not exist, I am dead; I feel I am absolutely nothing ... I am not alive, I cannot move; I have no mind, and no feelings; I have never existed, people only thought I did.²⁵⁵

One describes himself 'as if I were living in a graveyard'.²⁵⁶ Antonin Artaud described the severing of 'vital ties', 'a great cold, an excruciating abstinence' or 'living death'; he lamented a 'dispossession' of 'vital substance', an 'ebbing of my soul', associated with 'disorganisation' and 'constant leakage of the normal level of reality'.²⁵⁷ Disorganisation: *organisation* is the essential nature of an *organism*, which does not piece together, but grows its *organs*. Once there are no coherent enduring entities over time, reality ebbs away. This is a common trope in modernism, and is reflected in scientism and other reductionist philosophies. 'I walk like a machine', says one patient;²⁵⁸ 'I'm a psycho-machine', says another.²⁵⁹

Equally common is seeing others as not alive. Some examples gathered by John Cutting include:

on the underground all I could see were people in a car and they looked like ghosts, statues, monuments, dead people, as if cremated; people looked dead, pale, cold.²⁶⁰

One patient connects this deadness, this inanimacy with lack of embodied instinctual drive, the *élan vital*:

Everything around me is as if dead, like uninhabitable houses: I don't mean ruins, for they have a sort of poetry. No, I am insensible to all that. I do everything out of obligation. I eat with effort, for material life does not interest me. I pretend to love, I make the gestures, but I feel none of it. At times I'd be glad to be like others, but that cannot be. The world leaves me cold. Men are 'automated corpses' – my mother a gluttonous doll.²⁶¹

'We created everybody in a secret lab', claims a patient reported by Stanghellini, as though humans were robots.²⁶² As one patient puts it, 'everyone seemed to be walking around like zombies ... a cross between robots and people.'²⁶³ Hélène Jacob reported that people were putting on an act, and were no more than robots.²⁶⁴ Another reported that staff with which she was familiar had been 'replaced by dummies'.²⁶⁵ According to another subject, people look 'like toys'.²⁶⁶ The flip between *seeing* the dead and the devitalised, and *being* dead or devitalised is exemplified by a patient reported by Rachel Rosser: 'Perhaps my nervous tissue has been destroyed ... I used to think everyone else was an automaton. Then I saw them relating to one another and I realized I was the automaton.'²⁶⁷

In schizophrenia, because of the lack of distinction between the living, the dead and the never-alive, while living beings become disturbingly like zombies or machines, inanimate things can on occasion become disturbingly alive. (Worth remembering as we monitor our progress into twenty-first century 'Enlightenment'.) The patient Renée, commenting on what happens when objects have 'lost their names, their functions and meanings', notes that 'they became "things" and began to take on life, to exist'.²⁶⁸ But their life is terrible, predatory. She later records that 'I implored [my mother] to save me from the clutches of the Enlightenment and the animation of Things.'²⁶⁹

'Intelligence', writes Minkowski, referring again to the philosophy of Bergson, in which 'intelligence' means effectively the left hemisphere's grasp,

although it is the product of nature, has as its principal object inorganic matter. It can only reflect things which are discontinuous and immobile. It only feels at home when dealing with *dead* things.

[270](#)

The counterparts of this, too, can be clearly seen in early modernism. According to Wyndham Lewis, '*deadness* is the first condition of art ... as opposed to naked pulsing and moving of the soft inside of life, along with infinite elasticity and consciousness of movement, on the other ... The second is absence of *soul*, in the sentimental human sense ... It has no inside.'

[271](#)

Schizophrenic subjects also often complain that they have lost touch with their feelings or even with their body altogether: 'in general, I didn't have a sense of my body anymore; this completely vanished at some time.'

[272](#)

So Anne reported plaintively that 'all that is left to me is to rely on reasoning'.

[273](#)

She represents the model human being of cognitivist psychology – something very like *homo economicus*.

Man the machine

Morbid objectivisation of the body leads not just to devitalisation but to seeing it as specifically *mechanical*. A patient of Franz Fischer's complained that 'I am like a machine that runs standing still on the spot. It's being run almost to breaking point, but it stays just where it is.'

[274](#)

And again we see here the lack of traction between self and the world: the 'machine runs' at breakneck speed, but there is no movement in the subject's world (reminding one of Alice and the Red Queen).

Below is a picture entitled '*Corps humain*', the human body, drawn by a subject with schizophrenia, from which the head appears to be missing, though a tiny 'brain gland' (*Gehirndrüse*) and 'brow cavity' (*Stirnhöhle*) are indicated in amongst the various pipes and ducts:

Fig. 25. 'Katharina', Corps Humain (1965). Drawing of a human body, by a schizophrenic subject, showing internal organs and apparently without a head (Photo: Marie Humair, Atelier de numérisation – ville de Lausanne. Collection de l'Art Brut, Lausanne)

Minkowski had a patient who, as well as believing that sex could be reduced to mathematics also believed 'the human soul to be the result of an action of acids on the brain'.²⁷⁵ Sass describes a patient who spoke of himself becoming a 'more efficient communications machine'.²⁷⁶ If these

remarks from schizophrenic patients seem oddly familiar, it may be because this pathology is now embedded in the culture that surrounds us.

It is very common for people with schizophrenia to describe themselves as machines or computers, or as being controlled by forces emanating from machines or computers – so common that, in my experience, if the right questions are asked it can be found in at least half of all such patients. Sass had a patient who felt his mind was a ‘photocopy machine’.²⁷⁷ Many patients report believing themselves to be cameras, computers or other mechanical devices: ‘I saw everything I did like a film camera’;²⁷⁸ ‘I was myself a camera’.²⁷⁹ Another patient says that

no matter where, the observing was with everything I did ... For me it was as if my eyes were cameras, and my brain would still be in my body, but somehow as if my head were enormous, the size of a universe, and I was in the far back and the cameras were at the very front ... all is like a machine.²⁸⁰

A patient of Sass’s complains that ‘there’s nothing there, no cognition at all. I’m actually deluding myself into thinking I could think ... I was actually searching my memory bank ... non-mechanical thinking? I can’t conceive of that any more.’²⁸¹

The borderline between persons and computers is here, for such minds, fascinatingly blurred. At the same time schizophrenic subjects will doubt that anything exists apart from what they conceive in the hall of mirrors of their own mind. Parallels with both these positions, once again, from historical and, especially, contemporary philosophers, and cognitive scientists, hardly need to be laboured (‘deluding myself into thinking I could think’ neatly expresses the illogicality of one such position). For such patients, as for certain scientists and philosophers, the human being itself is reduced to a mechanism: thus according to one schizophrenic subject ‘man is merely a heap of memories in a standard hardware’;²⁸² to another ‘everyone is talking to each other and I can’t figure out the mechanism ... One day the day will come and we’ll see that it’s all quite mathematical.’²⁸³

While there are cognitivist scientists to whom that would seem to make perfect sense, and for whom it would even be a welcome advance, I doubt this means that schizophrenics are seers and philosophers with privileged

insight into the nature of being, any more than that they are spiritual masters; but that, more probably, there is something very odd that happens to the world once you view it in the way towards which our unbalanced analytic tradition in philosophy and our unbalanced technological tradition in science leads us, a tradition in which most academics now are so thoroughly schooled that they can't see that there is a problem, let alone how to escape it.

'The clock, as we have already mentioned, was not just a clock but an assemblage of instruments of torture – cogs, key, hands, pendulum, etc. *Every object that he saw was like a clock.*'²⁸⁴ So writes Minkowski of one of his patients. This was the fashionable Enlightenment view exemplified by de La Mettrie's *L'homme machine*, one which carries on effectively unaltered in the minds of many biologists. (It was also Paley's view of God: the watchmaker and his clockwork universe.) Once the body is foregrounded by the left hemisphere as a thing alongside other things to be observed and 'understood', as a scientist might observe a specimen, from without, it can no longer act as the intuitive, unquestioned and *continuous* basis of understanding itself.

In schizophrenia, subjects say that they find themselves, like scientists, 'not involved in the world, merely observing it from outside to understand its secret workings'; one finds himself 'a detached onlooker'; another reports that 'I am like an anthropologist.'²⁸⁵ Blankenburg's schizophrenic patient Anne complained bitterly that for her it was 'as if I examine the whole world-mechanism from the outside.'²⁸⁶ Descartes had aspired 'to be a spectator rather than an actor in all the comedies the world displays'.²⁸⁷ As Minkowska aptly remarks of schizophrenic subjects, 'they sit by like spectators on the life that plays itself out around them; they neither act nor feel'.²⁸⁸

As machines we are manipulated by others, by robot-makers, or puppet-masters (or nowadays 'selfish genes'). Hélène saw the living world as 'aspiring' to be a puppet theatre.²⁸⁹ Another woman with schizophrenia described other people as seeming 'so phony and lifeless and small, as if they could be manipulated in her fingers', and wondered whether they could be drawings, or perhaps marionettes, robots, or automatons.²⁹⁰ The patient Renée described other people similarly: 'around me, the other children, heads bent over their work, were robots or puppets, moved by an invisible

mechanism’.²⁹¹ A patient of Schilder’s reported: ‘I am quite mechanical. I have gone to pieces. I am like a marionette’ (see Plate 10[a]).²⁹²

As people become more like machines, machines become more like people – both in the modern world and in schizophrenia. Schizophrenic individuals often seem to inhabit the ‘uncanny valley’ – a term that virtual reality and video game designers use to refer to that unsettling, liminal realm in which one is uncertain whether something or someone is alive or dead, real or unreal.²⁹³ And machines produce their own version of time: ‘my head has become a clock, a machine, now I’m making time myself ... the new time is ... produced by the ... machine’.²⁹⁴

Bearing in mind the analytic tendency of the left hemisphere to pare the body down, in Zwicky’s phrase to ‘polished bone’, and given the way in which the left hemisphere offers a map in place of the terrain that is mapped, a patient treated by Minkowska is highly informative:

What upsets me a lot is that I have a tendency to see only the skeleton in things; it can happen that I see people in this way. It is like geography, where rivers and cities are lines and points ... I schematise everything, I see people as points or circles. When I think of a meeting I attended, I see the room, I represent the people present by points.’²⁹⁵

Living in a diagrammatic version of reality leads to seeing, in Eliot’s phrase, ‘the skull beneath the skin’.²⁹⁶ The psychoanalyst Eric Laurent describes a psychotic patient who ‘would see a skull on the face of the girl he was interested in, and his own skeleton through his skin during sex’.²⁹⁷ Again Hélène Jacob believed she was

an entirely transparent woman. (For this reason I have been contacted by today’s scientists, who are able to record every movement made by the circulation of my blood – my heart – lungs – bladder – guts.) ... All human bodily reactions, whether spontaneous or induced, can be reproduced as a diagram like an administrative map of the human body.²⁹⁸

The painter Edvard Munch, who was hospitalised for a paranoid psychotic illness, painted a self-portrait with his arm replaced by a skeleton (see Plate 10[b]). As readers would expect, it is the *left* arm; as it was when William Kurelek, a patient treated for schizophrenia at the Maudsley Hospital, represented his younger self in a detail of the astonishing painting of his psyche, *The Maze* (see Plate 11).

Against nature

The counterpart of a predilection for the mechanical is an alienation from – an aversion, even, to – whatever is *natural*.²⁹⁹ ‘I lost all sense of naturalness’, says one schizophrenic subject. ‘I can induce it or not with my own brain.’³⁰⁰ In parallel, the three-dimensional is replaced by the two-dimensional, the living by the mechanical and the natural by the artificial.

There is a positive distaste for what is natural and spontaneous (the right hemisphere’s realm), and an exaggerated concern with *utility* and the man-made (the left hemisphere’s realm). For Hélène Jacob, according to Tatossian, if places are not useful for something they are empty wastelands: she called them the ‘Africas’ of the whole world:

For Hélène, nature is Nothing, since she places herself irrevocably outside the world, which is experienced as exclusively ‘a complex network of tools’. Not in a single passage of her memoir, not even in its more lyrical flights, does Nature appear: Hélène has no ‘feeling for nature’ and this absence has existential meaning, not purely literary significance. Hélène’s favourite spaces are those of towns; or better, these are the only places ‘she can take seriously’.³⁰¹

Tatossian points out that towns alone are ‘good for’ something; providing housing, workplaces, welcoming tourists, facilitating trade:

in a word, they have a function, a ‘utility’, and by the same token render their inhabitants ‘tools’, good-for [something or other] ... nature, nature is useless and man feels himself useless in her presence.

She had plans to make everything, including the sea, *useful*, if necessary through tourism (her attitude is an uncanny anticipation of that of rural ‘development’ boards). Her world plan is the progressive extension of towns into the natural world, affirming “tool-being” [*l’être-outil*].’³⁰² In schizophrenia, as in modernity, there is a relentless antagonism towards nature – both in humanity and in the whole natural world.

According to Maurice Dide and Paul Guiraud, schizophrenia

is characterised from the outset, at an early age, by a collapse of the instinctual origins of mental life ... A weakening of the vital spirit and of emotional capacity is both the necessary and sufficient element by which we may characterise the illness.³⁰³

To my mind, all that we have looked at here approximates the bizarre, alienated condition enjoined on us today and reinforced by a toxic combination of bureaucratic and scientistic (not necessarily scientific) thinking with that of the philosophers and pseudo-philosophers of the School of Nothing Buttery: all tending to the view that we are machines. Nietzsche bemoaned the state of normal human beings, those semi-animals unhinged from instinct and no longer able to ‘count on the guidance of their unconscious drives’, being forced instead ‘to think, deduce, calculate, weigh cause and effect – unhappy people, reduced to their weakest, most fallible organ, their consciousness!’³⁰⁴ Nietzsche is describing the loss of intuition, or the right hemisphere’s take, which is wholly inadequately replaced by that of the left hemisphere. The schizophrenic is the apotheosis of this tendency in modern man: Nietzsche’s prototype of ‘theoretical man’ and his ‘determination to destroy myth’.³⁰⁵ Myth is otherwise known as the deep, embodied, imaginative understanding available to the right hemisphere – and seen by the left hemisphere as a lie.

Hyper-rationalism

When the natural flow of time has become stilted or stopped, and the intuitive sense of the whole disrupted, the only way in which things can be put together again is by lining them up according to the linear chains of logic. We saw that one schizophrenic patient thought that ‘people should

take inanimate matter as a model in order to constitute their firmness and the *rationality* of their movements.’³⁰⁶ Another says ‘everything I do, I do with logic and reconsideration ... Almost nothing works naturally, of its own accord ...’³⁰⁷ Kretschmer described the schizoid temperament as having ‘a certain tenacious characteristic, a tendency to the enumeration of names and figures, to numbering, and schematisation, to logical abstraction, and to the building of a system at all costs.’³⁰⁸

It is widely accepted that the autistic brain tends to excessive systematisation. This then leads to the substitution of rules and procedures for the intuitive, engaged, intersubjective understanding of the world that is no longer available: human affairs are seen as guided by specific rules, rigid principles and schemas – schemas that are insensitive, like bureaucratic procedures, to human meaning. Importantly, logic is entirely structural: it is utterly impervious to content. Ludwig Binswanger reports the case of a father who placed a coffin under the Christmas tree for his daughter, who was dying of cancer, because the coffin was, he correctly reasoned, something she was going to find useful – thus a very suitable present.³⁰⁹

Flow is what makes sense of life. When it disappears all that is left is the disembodied forms of logic. As Blankenburg commented, *logic*, in schizophrenic subjects, has to substitute for narrative as a way of linking things together. He finds this already apparent in his patients’ school exercises:

The patients still manage to solve difficult, intellectually demanding tasks without considerable effort. These are tasks, however, that do not require much interpretive skill. In this early stage, some patients retreat to the study of mathematics and physics. They try to replace the ‘natural successiveness or consistency’ of experience that rests on common sense with what are sometimes more – and sometimes less – ingenious logical constructions.³¹⁰

The Swiss psychiatrist Roland Kuhn reported on the case of a patient with schizophrenia called Franz Weber, who ‘wanted activity of any sort to be replaced by knowledge’. Thus motion in the physical world would be replaced by stasis and abstraction. It seems that he ‘disapproved of a life that neither here nor anywhere could be *defined*’:

The motivating direction of the patient's entire work was to take the ready-to-hand [*zuhanden*, embedded and implicit] stuff around him out of its fluid situation in the business of living, and turn it into something that was purely present-to-hand [*vorhanden*, static and explicit].³¹¹

He developed the idea that he must collect and store all the knowledge that had accrued to human beings over the millennia to save it from destruction: a recording project (I will come to this shortly). What struck Kuhn was that his patient devoted enormous energy to describing the structures and procedures involved – the architectural and administrative detail – but nothing whatever was said about the content: 'Franz Weber was not at all concerned with what his [researchers] wrote and illustrated in their annually published books', provided they 'get ready one book each year, complete with tables and figures, which, he specified, should be of a high artistic standard'. All this is familiar to any modern academic, and indeed must be familiar to anyone alive today in the West or the urban East. It is all consonant with an emphasis on the left hemisphere's take on the world: the triumph of procedure over meaning in every walk of life.

Another schizophrenic patient attempted to understand how to interact socially by scrutinising the details of other people's behaviour, as if he were some kind of technical observer, perhaps an anthropologist; he wanted to encode the steps involved in making friends and to devise 'new schemata' for relationships on his hospital ward.³¹² Other subjects speak of understanding from the outside like a scientist, attempting to make sense of others' mental states through observing everyday 'transactions', or 'scientific' analysis of the workings of 'intelligent mechanisms' ('I study people. I want to understand how they are inside ... I studied a system to intervene at the right moment in conversations').³¹³

The problem in schizophrenia is not a failure of logic, but the exact opposite: a hypertrophy of the logical faculty, with the loss of some crucial aspect of life, expressible as the common sense elements that are immediately comprehensible to a normal person. Blankenburg speaks of a 'loss of natural self-evidence'; Sass of the 'loss of ipseity', the naturally given 'core sense of existing as a vital and self-identical source of awareness and agency.'³¹⁴ One schizophrenic patient told Blankenburg that

‘I am lacking something very ordinary but important and common to all human beings, and I cannot even say what it is like.’ ³¹⁵ In a revealing survey of schizophrenic subjects, about a third endorsed the statement ‘what is most essential in humans is not working in me’. ³¹⁶ In all forms of dialogue today – everything from a conversation with an office employee to a debate with a politician – I feel these words find an application: in fact it often feels as if one is talking to a machine.

There is a deep connexion between excessively rationalistic thinking and delusion. I have quoted Louis Sass’s observation that the most deluded patients are the most logical. Delusion-prone individuals who are not formally mentally ill also jump to conclusions faster, but then jump the other way too fast, as well, in the light of disconfirmatory evidence. It is as if they had ‘a need for closure’, and could not tolerate ambiguity and uncertainty. ³¹⁷ Another way of thinking about the situation is that they have only the most tenuous grasp on reality; but that must inevitably go with not tolerating ambiguity and uncertainty. Either way, it suggests a failure of the right hemisphere’s grounding role in a world where nothing is certain.

There is an insistence on mathematical or numerical aspects of the world, a striving after illusory certainty, a ‘morbid geometrism’, a preoccupation with spatial arrangements in the world, and with symmetry, corresponding to a certain ‘lifeless rigid obsessionality’. ³¹⁸ Minkowski gives an account of a patient whose attitude is alarmingly close to the ambitions of some scientists, analytic philosophers and bureaucrats, representing a free-wheeling left hemisphere. ‘As far as I am concerned, a plan is everything in life’, the patient tells us:

I wouldn’t upset my plan for anything, I’d rather upset life than the plan. It’s a feeling for symmetry, for regularity which makes my plan so attractive. Life displays neither regularity nor symmetry, and that’s why I *fabricate* reality. All my strengths I put down to my brain.

What I am going to say will appear fantastic, but there it is. My state of mind now consists in trusting nothing but *theory*. I can believe in something’s existence only when I have *demonstrated* it. For example, a

woman's body produces an effect on a man. Why? There's an example of something that I doubt, because I can't succeed in demonstrating it. I can't see myself trusting only to my impressions.³¹⁹

Sometimes, after seeing a woman in the street that made an impression on him, he would go home and sit down, in a maximally symmetrical posture, and try to reduce the problem to mathematics. Thus even sexual feelings might one day, he hoped, be abstractly codified and accounted for – though he found the problem prodigiously difficult because his analysis soon entered into an infinite regression. He felt sure that the body could be reduced to geometry, and that therefore – a sphere being the perfect shape – it was clear that the perfect shape to which the human body might aspire was that of a sphere.

In the world of the schizophrenic subject, mathematical criteria are applied to determine the value of objects and events – again, not unlike the mindset of modern bureaucrats – solely in terms of their measurable dimensions or geometrical characteristics. 'My intellectual parts became the whole of me', says one man with schizophrenia.³²⁰ Bergson's 'intellect', the left hemisphere, goes it alone; and it does not understand life. Blankenburg's Anne reported that 'it is impossible for me to stop myself from thinking';³²¹ as Sass and Parnas point out, 'her constant need to think was, however, accompanied by a constant inability to understand.'³²²

Blankenburg describes such patients as experiencing an impoverishment of all vital relationships apart from the reflexive relationship to oneself.³²³ And that too is impaired at times. Another schizophrenic subject reports that

apart from my reason, which is intact, everything else is in complete disarray. I have suppressed my emotions as I have all aspects of reality ... I don't feel things any more. I don't have normal sensations. I make up for this lack of sensations with reason. Since my illness began I have suppressed the impression of time. Time doesn't matter any more ... I feel that I can reason quite well, but only in the absolute, because I have lost contact with life.³²⁴

Once everything has to be worked out, calculated from first principles, life comes to a juddering standstill. The normal 'taken for granted' quality

of authentic experience in the flow of time is lost, and in its place everything is doubted. Another schizophrenic subject, described by Thomas Fuchs, began by doubting that his familiar possessions were still his from moment to moment. He moved on to doubting that his arms were his (once again we are reminded of Descartes, who doubted he had a body):

He had to carefully observe his arms from the hands up to the body in order to make sure that they were his own, and he repeatedly looked behind himself in order to see if there was not somebody else who moved them. Now he could not trust his own hands any more, and doubted the simplest actions ... Every *movement was like an arithmetical problem* that had to be pondered over with extreme concentration. So he became stuck in his everyday performances and felt more and more desperate.³²⁵

Literalism

When you doubt everything, all meaning that is not literal and unambiguous becomes a threat: how to make sense of it? The psychotherapist Darian Leader describes a man whose grip on reality became so tenuous after his father's death, that he became radically unsure of all meaning, and was obliged to carry 'a huge dictionary' strapped to his back wherever he went.³²⁶ We know that in schizophrenia there is a degree of literalness (as distinct from concreteness), that comes from an inability to understand metaphor, and goes with 'thingification' (reification). Both people with autism and schizophrenia may become preoccupied with the goal of attaining certainty of meaning, and tend to be literal-minded. They are, once again, similar to right brain-damaged subjects in this respect (see Fig. 19).³²⁷ A patient, observing that he was lacking 'a *seat* in my life', started building an armchair on which he engraved proverbs, so as to 'have his place, like the others, in everyday life'.³²⁸ Another made a present of a wine-stopper to her analyst, believing him to be an alcoholic like her father, and that a wine-stopper would 'stop' him drinking wine.³²⁹ And, since we are speaking of literal-mindedness, Leader also records that a group of patients at a French hospital asked their psychiatrist if they could have the Name-of-the-Father implanted surgically in the brain, after they heard it

was absent in psychosis.³³⁰ It is hard to get less literal than the Name-of-the-Father (*le nom du père*), a fantastic abstraction invented by Jacques Lacan, as part of his imaginative, but unsupported, schema for explaining psychosis as an imperfect separation from the mother. A triumph of literal-mindedness, an inability to deal with the purely implicit, and indeed a fear of humour (as dangerously dealing in the implicit) are also identifiable in public discourse today.

Hyper-consciousness

A defining element of the modern predicament is a degree of hyper-consciousness that inhibits our ability to tap into embodied skills and intuitive wisdom – making us ever less spontaneous (everything must be passed, checked and planned beforehand). The problem is that the left hemisphere is foregrounding something that must, to be effective, remain in the background. We have lost awareness of the importance of the spontaneous and implicit. And so it is in schizophrenia. Here are five different patients speaking:

- None of my movements come automatically to me now. I've been thinking too much about them, even walking properly, talking properly and smoking – doing anything. Before they would be able to come automatically ...
- People just do things, but I have to watch first to see how you do things ...
- I have to think of what I am going to do all the time and that takes up a lot of energy and when I am doing something I am aware of my every movement ...
- I have to do everything step by step, nothing is automatic now. Everything has to be considered ...
- I am not sure of my own movements any more. It's very hard to describe this but at times I'm not sure about even simple actions like sitting down. It's not so much thinking out what to do, it's the doing of it that sticks me ... ³³¹

This spotlighting, or focussing in on, what should remain in the background lies behind many schizophrenic symptoms; in keeping with this, figure-ground perception is impaired in schizophrenia, especially in those with ‘negative’ symptoms.³³² (‘Negative’ symptoms refers to the absence of something present in normal subjects – eg, a loss of motivation, or of affect; ‘positive’ symptoms refer to the presence of something absent in normal subjects – eg, hallucinations or delusions.) This in turn is consonant with the loss of visual depth that is experienced in both schizophrenia and right hemisphere damage.

Minkowska reports that for one patient ‘everything has to correspond to a plan fixed in advance: “I can’t trust to chance”, he says, “one must have foreseen everything”.’³³³

Of another, ‘all idea of chance, coincidence, of unintentional or unconscious acts was wiped out for the patient’, writes Minkowski.³³⁴ This loss of spontaneity alienates one from life itself. Whenever ‘an individual’s sense of the flow of life has come to a stop or been frozen’, writes Binswanger,

... that person can no longer realise himself, no longer mature, and will lose the capacity to make rapport and emotional contact with others ... The connection between *manneristic behaviour* and schizophrenia is a particularly close one. It can be regarded as a ‘loss of sparkle’, a freezing and *repetition* of present existence, and a reflection of the intellectual side of man’s nature rather than the ‘free play’ of individual life forces. It is as if there is an ‘iron net’ round the free expression of gestures, an invisible and incomprehensible force which is stifling the natural flow of life ... Minkowski’s patient [the patient who thought that even sexual sensations were reducible to mathematics], a school-teacher who rigidly applied certain pedagogic principles without regard to whether they were appropriate, is another example of how schizophrenia desiccates and denatures existence, leaving only a shell or a mask of what life is really about.³³⁵

I would ask the reader again not to be so literal-minded as to see this only as an expression of an illness, but also of the way the world begins to

become when we privilege the left hemisphere's take at the expense of that of the right.

Representation

I have mentioned the loss of flow several times. We saw in Chapter 2 that flow in time sometimes becomes a succession of still frames in right hemisphere damage. Loss of the sense of flow, particularly in time, has been repeatedly fingered by many distinguished psychiatrists as the core abnormality in the psychopathology of schizophrenia, from which all others stem.³³⁶ Normally, for the rest of us, when time itself is experienced, it flows seamlessly; when it is *re-presented* – the business of the left hemisphere – it is spatialised: become a line in space that can be retrospectively broken up into segments. Because of our reliance on visual re-presentation of time, we too have come to see it spatialised in clocks and watches, either analogically or digitally. Since this topic is so important, necessarily involves an exploration of the nature of time in its own right, and graphically illustrates the importance of how we come to understand time, I will postpone a discussion of the experience of time in schizophrenia to a later chapter (Chapter 22). For now it is enough to note that the experience of time breaks down.

With the loss of time, flow and continuity, Binswanger noted that only 'a shell or a mask' remained of what life really is. That 'we are the hollow men', mere husks, is a modernist theme, and a common element of schizophrenia ('no inside of the body, but only a frame'): the substance is gone and only an empty structure remains. Presence relies on the right hemisphere, and in its overshadowing by the left hemisphere, re-presentations take over.

The confrontation with representations only, not with the felt presence of what is living, results in a sense that all is mere shadow play, insubstantial and ultimately unreal. Rather like the fabled Potemkin villages – façades supposedly erected along the route taken by the Empress Ekaterina, only to be taken down after she passed and hastily reconstructed further along the banks of the Dnieper in order to impress her – Sechehaye's patient Renée describes 'paste board scenery of unreality ... even the sea disappointed me a little by its artificiality.'³³⁷ The sea? In a similar way

Schreber found that at a station people merely ‘gave the impression of being’ railway passengers; the people who attended him in hospital were merely ‘fleetingly got up’, like mannequins.³³⁸ One of Louis Sass’s schizophrenic subjects thought farmers were not really tending the fields, but simply going through the motions,³³⁹ putting one in mind of the account by Demay and Renaux of a head-injured soldier according to whom the whole First World War was make-believe, an elaborate performance.³⁴⁰

This trope is common in modernist novels and films: it forms the basis of the well-known film *The Truman Show*. More generally, the confusion between the plane of representation and the plane of the reality that is being represented is behind the breaching of the ‘fourth wall’. It also underlies the vision of reality as just the projection on the walls of a prison cell in the head: there is no direct perception of and no direct contact with the world. ‘On the contrary’, write de Haan and Fuchs,

instead of directly seeing something, they looked at images transmitted to them by a camera ... and they themselves were far away from the world where these images originated. This distance between the subject and his experiences conveys the classical picture of a homunculus sitting ‘at the back of the head’.³⁴¹

In losing reality, things become mere representations, abstract generalities, and in becoming abstract generalities they lose their reality. We have seen that a loss of uniqueness is strongly associated with damage to the right hemisphere, and so it is compromised in schizophrenia: ‘an individual’s existence is losing its personal quality and uniqueness and becoming a mere *copy* of some general way of life’, writes Binswanger. ‘A person loses his individuality and becomes typical of a certain class of people.’³⁴² Engagement with real persons is replaced by a utopian interest in abstract humanitarian values: ‘I love Mankind, but I detest humans’.³⁴³

According to a patient of Minkowska’s:

I have managed to detach myself from the realm of the material, and in my actions I am guided by impersonal principles. I respond not to a limited environment, but to the whole world. I’ve come to live for the idea and look on people impersonally. I’ve been united in

thought, not with human beings, but with humanity, and sought as far as possible to attain the absolute. I've submerged my filial love in a greater love.³⁴⁴

This too is not confined to schizophrenia: it is a matter of observation that those who espouse grand theories supposedly based on love for mankind, are by no means the kindest people one meets; and those that are innately suspicious of such schemes often surpass them in generosity and kindly warmth towards actual human individuals.

The imaginary lover of Tatossian's patient Hélène Jacob is blended with the son of Marie Stuart, the Duke of Gloucester and other public figures, had starred in a film with Charlie Chaplin, but was also entirely generic: 'the man of iron, of the World of Today and Tomorrow – the One and Many of the Sciences', and so on: 'he will be my liberator and the Liberator of the human race.'³⁴⁵ He was also in everyone and everywhere, in every word that was spoken on the radio.³⁴⁶ Her own father would have become one of the 'Great Eminences of this World', like Stalin.³⁴⁷ In the words of Minkowska:

For an individual who does not feel, does not act, does not trust his impressions, but merely thinks, reflects, analyses, looks for proofs – and never embraces the whole, but breaks everything down into little details – the fatal consequence is that all is reduced to a mental *representation*.³⁴⁸

The world is once more flat

Everything comes to be a representation: not just that time is spatialised, but that space comes to lack depth. In both time and space there is a dimension missing, the one that gives depth. One of Fischer's patients reported that three-dimensional reality had flattened into a two-dimensional image:

I was as if cut off *from my own past*. As if it had never really been, just shadows ... Then the past switched round: everything got mixed

up, but not in any way you could understand ... it was as if a picture with *depth of perspective collapsed and suddenly flattened*.³⁴⁹

Here are another four patients, all of whom express the ‘inauthentic’ nature of reality as mere representation:

- He used to be a drawing in a book but had finally escaped and come to the hospital ...³⁵⁰
- Everything lies in one line, there are no distinctions of depth any more ... Everything is like a motionless surface ...³⁵¹
- Things are no longer the way they used to be. They are strange, as if they only were silhouettes ...³⁵²
- [The world is] like a photograph ...³⁵³

I mentioned at the outset that to spatialise time is to kill it. There is in schizophrenia ‘a pathological predominance of criteria and elements of a spatial order to the detriment of vital dynamism.’³⁵⁴

La machine infernale

Remember Binswanger spoke, in one and the same phrase, of ‘a freezing and *repetition* of present experience [his emphasis]’. When time stands still, this leads to lifelessness, and monotony – but to *repetition*? Though repetition induces a sense of lifelessness and monotony, the one thing that can’t happen if time stands still is repetition. But to the schizophrenic subject everything seems to be a re-presentation of something else *immediately that it happens*. All that is *is* the representation, since, for the schizophrenic subject, the original no longer exists. Nothing is ever truly fresh, new, creative; for that the right hemisphere needs to be functioning normally. Everything has the air of familiarity from the word go, because everything is experienced left hemisphere fashion: after the fact, already known, as something that is from the outset already represented – and therefore *repeated*. Remember the patient who saw ‘the future as a repetition of the past’. It is already tired, generic, categorised, drained of life.

Minkowski, explicating Bergson, remarks:

From the very fact that it is always striving to reconstruct what is there, intelligence [LH] cannot capture what is new at any moment in history. It has no room for the unpredictable. It rejects anything creative. Preoccupied only by repetition and similarity, intelligence cannot appreciate the changes produced by time. It ignores the fluidity inherent in things, and petrifies everything it touches.³⁵⁵

The left hemisphere world, we have seen, gets ‘stuck in set’. The right hemisphere plays the decisive role in avoiding repetition.³⁵⁶ Here it is worth comparing the speech of the disconnected left hemisphere in split-brain patients, which is not just lacking in emotional nuance, but remarkably repetitious. Dimond comments:

It is a surprising experience to revisit these patients after two years to find many of them saying almost exactly the same things, and in a virtually identical manner as on a previous visit ... *time stands still* not only because of poor memory but rather because the same thoughts, the same mental content, are still circulating in much the same way.³⁵⁷

Indeed ‘reality, as it was formerly, no longer exists’, says another: ‘real life has suffered a decline.’³⁵⁸ I am forcibly put in mind of Walter Benjamin’s saying already in 1936 that in the modern era ‘experience has fallen in value. And it looks as if it is continuing to fall into bottomlessness.’³⁵⁹ And of Ferdinand Kürnberger’s dictum ‘*das Leben lebt nicht*’ – ‘life doesn’t live’.³⁶⁰

Consequently there is a need to re-present constantly – the left hemisphere’s mode of being – after the fact – in an attempt to produce continuity. This is like Descartes’ remark that the world must be constantly reconstructed at every moment or it disappears. Indeed, one of Jaspers’ patients actually says ‘the world must be *represented* or the world will disappear’.³⁶¹ One schizophrenic subject felt he must actively put together the fragments of time which he captured in photographs in order to reassure

himself that the world existed.³⁶² And hence comes the very modern necessity of *recording*: repeating experience in representation. No longer present and hence experienced, time for the left hemisphere becomes a frozen record. ‘We see’, writes physicist Lee Smolin, ‘... that the process of recording a *motion*, which takes place in time, results in a *record*, which is frozen in time – a record that can be represented by a curve in a graph, which is also frozen in time.’³⁶³

One patient, a single unemployed man living alone, photographs the landscape that he sees from his window – this is his sole employment. Repeatedly he shows these photographs to his psychiatrist and comments: ‘Here there is a car ... there the car did not move during the night ... This is the same car on another day, there are dead leaves on the roof.’ He comments, ‘Time goes by, things do not change. *I find time with photographs.*’³⁶⁴

Daniel Schreber experienced, like many schizophrenic subjects, ‘influencing rays’:

the approaching rays were sent down with the phrase, ‘We have already got this’, *scilicet* [that is to say] written-down ... For example, when I saw a doctor my nerves immediately resounded with ‘has been recorded’, or the senior attendant – ‘has been recorded’, or ‘a joint of pork – has been recorded’, ‘railway – has been recorded’ ... All this goes on in endless repetition day after day, hour after hour.³⁶⁵

The first book-length account in English of a psychotic subject is John Haslam’s description of James Tilly Matthews, a patient at the Bethlem Royal Hospital, popularly known as Bedlam, published in 1810. Its original title was *Illustrations of Madness: Exhibiting a Singular Case of Insanity, And a No Less Remarkable Difference in Medical Opinions: Developing the Nature of An Assailment, And the Manner of Working Events; with a Description of Tortures Experienced by Bomb-Bursting, Lobster-Cracking and Lengthening the Brain. Embellished with a Curious Plate.*³⁶⁶ Matthews, a London tea merchant, believed he had unearthed a conspiracy that involved heads of state all over Europe and was leading to tumult, revolution and war. His mind and the minds of others were being controlled

by an elaborate machine which he called the 'Air Loom', manipulated by men with bellows and emitting influencing rays that controlled his every movement, and led to unpleasant bodily effects ('bomb-bursting', 'lobster-cracking', 'thigh-talking', 'fluid-locking', 'stone-making', 'brain-saying', 'knee nailing', 'vital tearing', 'fibre ripping' and 'apoplexy-working with the nutmeg grater'); and he illustrated it with precision worthy of an architect or engineer. (It is perhaps worth noting that an heirloom, an object valued for the fact that it is an embodied connexion between a succession of individual human lives over a stretch of time, should become paronomastically transformed into a timeless mechanism dealing in immaterial air.)

Fig. 26. The Air Loom, engraving by John Haslam, based on a machine described by James Tilly Matthews (from Haslam 1810)

My reason for referring to it here, though, is that it was the job of one of the imaginary gang, Jack the Schoolmaster, to be the recorder of everything that took place. All Matthews' experience was meticulously recorded. In fact the recorder can be seen at his desk, in the illustration, just beyond the *machine infernale* (see detail in Fig. 27). This may have something to do with the note-keeping that was part of the formalities of those attendants in whose care he was placed, but it seems far more essential than that. As Haslam, the apothecary, took notes on Matthews, Matthews, the patient, took notes on Haslam: much the same is true of Schreber's relation with his attendants. But that in itself is not without its significance. It is the beginning of systematic record keeping that forms the basis of any bureaucracy. (One of the most chilling aspects of the Holocaust is the bureaucratically meticulous, scientifically 'objective', recordings of deaths in the camps.)

Fig. 27. Detail of Fig. 26, showing the recorder, Jack the Schoolmaster

‘The voices and so on were not that important’, says one patient with schizophrenia. ‘I think that the enduring and pervasive feeling of being unreal is the disease itself. When I realised this condition of looking at myself *as in a movie* was permanent, I understood it would eventually destroy the core of my life.’³⁶⁷ And Tatossian’s patient H       saw herself involved in a gigantic *picture*, ‘where all that I think is *written down in black and white* ... before the eyes of the whole universe’.³⁶⁸ A modern dystopic fantasy – or is it becoming the reality?

There is a saying in modern ‘managed’ hospital medicine, designed to stress the importance of keeping accurate records: ‘if it’s not recorded, it didn’t happen’. (Interestingly, for the Greeks, while literacy was still not common, live testimony was required to affirm the truth of a piece of writing, not the other way round.)³⁶⁹ While this is a necessary part of accountability, and is not in itself reprehensible, it does actually state that representation is more real, at least in some contexts, than what actually happened at the time. Nurses and other care-givers have to spend so much time recording what they do that they have little time left in which to do it; the police are similarly handicapped, and I suspect that not even the self-employed are able entirely to escape this blight on life. The record is frozen, but life has flowed away, as life does. And in our left hemisphere-dominated, record-obsessed age, I have heard people say the same thing about taking photographs of their lives: ‘if it isn’t recorded, it didn’t happen’.

The habit of mind has spread into the fabric of life itself. One celebrated photographer was made miserable for years by seeing a natural scene so beautiful that, to him, it demanded to be recorded, at a moment when he had no camera with him.³⁷⁰ I mentioned earlier that one might think of left hemisphere prepotency as like confusing the map with the world that it maps. Social media, with its endless recording of the trivia of daily life, often seems like that. A Spanish professor of animal physiology, a presumably intelligent man, records everything – *everything* – he does. ‘It occurred shortly after turning 40’, he says. ‘I was looking back on my life and wondering what did I have to *show*?’ (Literally to ‘show’ for his life: there is an alliance here with the man who didn’t have a *seat* in life.) So he started writing down everything he did, saw, ate – thus ensuring that he would have nothing whatever to show for the rest of his life, apart from the fact that it had been recorded. Then he started taking photographs every 30

seconds. He has now accumulated more than a million photos. Unsurprisingly, he says he ‘hasn’t seen a lot of them ... It’s almost too much to go through.’ He admits that ‘really my devices, looking back, tell me little, except that intensity is hard to capture.’³⁷¹ The pointless details overwhelm and kill. Sterne was the first to spot and parody this modern tendency in the mid-eighteenth century: now we have Facebook accounts of the minutiae of empty lives.

At such moments two things come to mind. One is Faust’s pact with Mephistopheles, the most famous lines in German literature:

Werd’ ich zum Augenblicke sagen:
Verweile doch! du bist so schön!
Dann magst du mich in Fesseln schlagen,
Dann will ich gern zugrunde gehn!

(‘When I say to the moment “Stay a while, you are so beautiful”, then you can shackle me in chains: then I will gladly perish.’)³⁷² And the other is Blake’s

He who binds to himself a joy
Does the wingèd life destroy;
He who kisses the joy as it flies
Lives in eternity’s sunrise.³⁷³

This is not just a ‘Romantic’ insight. Here are lines from Bashō, the great seventeenth-century Japanese poet of *haiku*:

To stop a thing would be to halve a sight or sound in our heart.
Cherry blossoms whirl, leaves fall, and the wind flits them both
along the ground. We cannot arrest with our eyes or ears what lies in
such things. Were we to gain mastery over them, we would find that
the life of each thing had vanished without a trace.³⁷⁴

Freezing time kills. Our age is one of re-presentation: photography, sound recording and film have become so important to us that they can

come almost to supersede direct experience. We talk about an aide-memoire, as though we were preserving a memory. But research shows that photographs actually erode memories.³⁷⁵ The effect of taking photos is that they *substitute* for memories, as you can verify by thinking back to any travels you made some years ago of which you still have photographs: the photos tend to crowd out memory of all else. And time is sliced.

Nothing flows: continuity vs countability

Figures are particularly attractive to many people with autism. In many, but not all, cases this seems to go with seeing numbers as absolutes, rather than as relationships – they can of course be seen as either. Jedediah (sometimes Jedidiah) Buxton, an eighteenth-century autistic *savant* from rural Derbyshire, who had quite amazing powers of mental arithmetic, though he was illiterate and could not even sign his name, calculated the product of a farthing (the 960th part of a pound) doubled 139 times. The result, expressed in pounds, extends to 39 figures. He afterwards multiplied this enormous number by itself. He astonished the Royal Society in London with his capacity for carrying out calculations of unbelievable complexity. While in London, he was taken to see Garrick performing in Shakespeare's *Richard III* at Drury Lane, which must have been an astonishing experience for a poor labourer from a rural backwater in the middle of the eighteenth century. But he was unable to focus on anything but numbers. After the play he was asked whether he had enjoyed it. He had nothing whatever to say about the drama, the acting, or the human tragedy, instead noting merely that the actors had spoken 12,445 words, and that 5,202 steps had been taken during the dances.³⁷⁶ In an observation which reflects the difficulty autistic individuals experience in broadening focus so as to take in several stimuli at once and make global sense of them, he reported, after hearing 'a fine piece of musick, that the innumerable sounds produced by the instruments had perplexed him beyond measure'.³⁷⁷

Things that flow have only artificially imposed beginnings and ends, and so defy enumeration. If the frame-freezing mentality of the left hemisphere takes over, the flow is replaced by any number of countable steps. The trouble is the countable steps can be measured but they are simply not the dance or the play. In a fascinating move, again redolent of

both scientism and contemporary culture, for some subjects on the schizo-autistic spectrum, if it can't be *measured*, it doesn't exist. A patient of Minkowska's, a teenage boy, reports:

The gym teacher had taken my measurements: but not the measurements of my legs, which led me to think that my legs were somehow mutilated. *In reality to me the absence of measurements of my legs meant the absence of legs.*³⁷⁸

Sass quotes a schizophrenic patient: 'I feel as if I've lost the continuity linking the events in my past. Instead of a series of events linked by continuity, my past just seems like disconnected fragments. I feel like I'm in the infinite present.'³⁷⁹ The 'infinite present' is nothing like 'always being present' – nearer to being the opposite: *never* truly being present at all, because of being outside the flow of time. The narrative of a life, which gives meaning to the self, is no longer recoverable.

We have seen that the right hemisphere understands narrative, where the left hemisphere has difficulty. Like right hemisphere-damaged subjects, autistic people show impairments in both generating and comprehending narrative, as do people with schizophrenia.³⁸⁰ Narrative is indeed the ground of human meaning; but this is not to say, incidentally, as it is sometimes presented by psychologists and philosophers, that we *invent* fictional narratives and therefore *invent* meaning, which we paint onto our lives like a mural, in order to shelter us from its barrenness. Narratives are not scientific facts but may be more true to life than any scientific facts can hope to be. It is true that we shape and tweak the narratives of our lives according to our assumptions. But they are more properly said to be discovered than invented. It is the left hemisphere, which does not understand narrative, not the right, that wholly makes up 'stories' to fit circumstances it does not understand. Michael Gazzaniga calls it the interpreter precisely because of this propensity confidently to make up something, plausible or not, to explain a set of circumstances it cannot account for. Life, rather, has no need of *extrinsic* meaning because to those who intuit and are alive to the implicit it has a wealth of *intrinsic* meaning, and spontaneously occurring narratives are the best way to embody that meaning, to communicate it and to celebrate it. Those who can operate only

explicitly – essentially those somewhere on the schizoid-autistic spectrum – have difficulties understanding human meaning of any kind. To them narratives are somewhat alien, and stories are lies (as children say, ‘telling stories’); they are ‘fables’, ‘myths’ – words that once denoted truths, but which now suggest deceptions.

At times the self is experienced as split in half (a phenomenon known as *Ich-Spaltung*) or alternatively duplicated. Hélène Jacob felt herself ‘*dédoublée*’ – a word which can mean either ‘duplicated’ or ‘split in two’.³⁸¹ This can be seen as a version of the Capgras phenomenon applied to the self. Because there is no continuity, change means not natural progression, but the substitution of one unchanging entity for another. A patient of Kimura’s reports

I am not able to *feel myself* at all. The one speaking now is the *wrong ego* ... When I watch television it is even stranger. Even though I see every scene properly, I do not *understand the story as a whole*. Each scene *jumps* over into the next, there is no coherence. Time is also running strangely. It falls apart and no longer progresses. There arise only innumerable separate *now, now, now* – quite crazy and without rules or order. It is the *same with myself*. From moment to moment, various ‘selves’ arise and disappear entirely at random. There is no connection between my present ego and the one before.³⁸²

One remembers that ‘no connection between my present ego and the one before’ is a position argued for by some modern analytic philosophers.³⁸³ It is also implicit in Descartes’ conception of time as constantly renewed instants.

Loss of the sense of reality

In this alienated state, the glue that holds the self together disintegrates. There is ‘a constant feeling that my self no longer belonged to me’, complains one patient:

The real ‘me’ is not here any more. I am disconnected, disintegrated, diminished. Everything I experience is through a dense fog, *created by my own mind, yet it also resides outside my mind*. I feel that my real self has left me, seeping through the fog toward a separate reality, which engulfs and dissolves this self ... I am an automaton, but nothing is working inside me ... ³⁸⁴

Note that the patient claims that experience is simply created by the mind, and yet that one does not even have the comfort of living it – instead standing somehow outside one’s own experience, observing, not inhabiting it. I suggest this is highly characteristic of the left hemisphere’s world-picture. Because its ‘experience’ is not in touch with the presencing of life known to the right hemisphere, and it therefore experiences its own *representation*, it seems to itself to live in a self-enclosed theatre, where experience is projected on the walls of the cell: ‘created by my own mind’, like the world as imagined by certain philosophers and psychologists. ³⁸⁵ In fact another patient gets even closer to a position promulgated by a number of popular materialist philosophers: ‘the world is an illusion *because* it’s seen through a brain’. ³⁸⁶ And *because* it is dealing with a representation, it feels itself to be somehow outside the experience, and the normally experiencing self dissolves, leaving just a husk, a mechanism, in its place. To the right hemisphere, by contrast, what is experienced carries with it the stamp of authenticity – it is in contact with something beyond the mind, not just invented by it; and yet it is also experienced from *within* – not at a distance, and from without.

The hall of mirrors

The world now becomes self-enclosed in such a way that symbols refer to other symbols, signs to other signs, ideas to other ideas, language to other language, without so to speak breaking out of this hermetic space to what lies beyond. What is true is what it says ‘on this piece of paper’. ‘There is a pane of glass between me and mankind’, a schizoid patient remarked, an observation which Kretschmer describes as of ‘extraordinary significance’. ³⁸⁷ ‘A wall of brass separates me from everybody and everything’, more forcibly wrote Margaret Sechehayé’s patient, Renée. ³⁸⁸

Under such circumstances, words can lose their purchase on reality and begin simply to refer endlessly to one another, another position that used to be fashionable in humanities faculties. Patients are more likely to experience a partial or complete divorce of word from meaning, of signifier from signified, such that words can begin to appear absurd or meaningless.³⁸⁹ Words may be treated, Humpty-Dumpty fashion, as having slipped their moorings in the shared world and become subject to the will of the omnipotent subject to mean whatever he likes; or alternatively as imbued with some magical power, and having a life of their own.³⁹⁰ Again there is an only apparent duality here, which in fact reflects the same underlying problem, a loss of connexion between mind and world. We are back to the loss of betweenness. When the right hemisphere is not functioning well, all is reflected back internally. 'My world sometimes felt like a distorted house of mirrors', complained one schizophrenic patient, 'reflecting infinitely inward upon itself.'³⁹¹

The loss of vital contact with reality leads to a sense of simultaneous omnipotence and impotence, grandiosity and cosmic insignificance, in schizophrenic subjects. Solipsistic subjectivity on the one hand (with its fantasy of omnipotence) and alienated objectivity on the other (with its related fantasy of impotence) tend to collapse into one another, and are merely facets of the same phenomenon. Both imply isolation rather than betweenness, the vital tension that gives authenticity to experience. If the world is truly bounded in your nutshell, then you are as good as king of infinite space. If our private experience is reduced merely to physics, its value is destroyed, just as physics is destroyed by being reduced merely to private experience. If I am everything, there is no reality to contact, and nothing for me to influence; if I am nothing, I cannot contact reality, and I can, by definition, have no influence. Both conditions lack the normal sense we have of ourselves as happily limited, defined by the relationship we have with others and the world 'beyond' ourselves.³⁹² What is missing altogether is the second person voice.

As Pascal put it, evoking a less grandiose conclusion than either of the histrionic alternatives:

Let us, then, understand our condition: we are something and we are not everything. Such being as we have removes us from knowledge

of first principles, which arise out of nothingness. And the smallness of our being conceals from us the sight of the infinite.³⁹³

One of the features of left hemisphere thinking is its tendency to ‘either/or’ thinking, while missing the ‘maybe’ area altogether. This tends to be replicated in schizophrenic thinking. It is very unusual for a person with schizophrenia to say ‘maybe’, or express qualified assent or dissent. If and when they do, you know they are decidedly on the mend. As Hölderlin developed schizophrenia, he incidentally invented the word *pallaksch*, meaning *either* ‘yes’ or ‘no’ – but never ‘maybe’.³⁹⁴

Only the right hemisphere is able to see that what seem to be opposites coexist and are necessary to one another – indeed, that by stepping beyond mere opposition, and excluding neither, a new unity can be attained. This will be explored in greater depth in Part III, where it helps to illuminate the foundational elements of reality. The left hemisphere is unable to accept that what it sees as opposites not only do not necessarily cancel one another out, but cohere. When the cohesive vision of the right hemisphere is lost, the left hemisphere seems to sense something is missing and strive for it, but in doing so veers, unstably, from one pole to the other, thus reinforcing the sense that the world is meaningless, perplexing and uncanny.

On the one hand the patient may experience himself as what Sass describes as the ‘subjectless subject’, describing simply a mass of impressions (a little like the ‘characters’ in Virginia Woolf’s *The Waves*), without the coherence that would be given by a unique living mind-and-body with a personhood and history. On the other hand he may seem convinced that the only way to understand anything, including himself, is by geometric pictures and diagrams, or mathematical rules, that ensure ‘objectivity’: pictures or diagrams which are meaningless because of the lack of connexion to a coherent experiencing subject. According to Ernst Kretschmer, schizoid people are ‘full of antitheses, always containing extremes, and only missing out the means’.³⁹⁵ As we have seen, subjects may complain of being imprisoned in the self and yet of their physical bounds being invaded; they often see living beings as mechanical and yet may see inanimate objects as having a life of their own. Although each of these pairings look like opposites, they in every case have a common nature. And although, as a group, they seem to concern a number of distinct elements, they are related to one another, and could be seen as different

facets of the same disturbance, in which the cohesion of self-and-world falls apart, and – whether as cause or consequence – the cohesion of each, the self and the world, also falls apart. Like a hologram, the whole is reflected in every (apparent) part.

Finally, at the core is one other important dipole, since the theme of this book is what we can reasonably hold to be true: belief and disbelief. As Sass has observed, the schizophrenic subject appears to occupy extremes simultaneously: both sceptical to the point of paralysis about matters that must be taken for granted if one is to function at all, and yet gullible enough to espouse enormously improbable belief systems that are clearly delusional. Once the theoretical mind is untethered from the body and community, in which it is grounded, and from which it receives its intuitions, there simply is no longer any solid basis for discriminating truth from untruth. And once again one sees parallels in some kinds of contemporary philosophy, and some kinds of belief systems driven by the irrationality of identity politics, which lead subjects to doubt everything except the validity of a bizarre conclusion which they feel driven to accept by formal rules. But never doubting the rules.

SUMMARY

If you have hitherto been reading summaries only, this might be a chapter to pause on and delve into, because no summary can convey the richness of the living material from the mouths of patients, conveying something both very strange, and increasingly familiar to those of us living in the modern Western world: what happens when the right hemisphere's contribution to understanding the world is neglected.

There are extensive and very striking points of similarity between the changes that happen to the experienced world consequent on right hemisphere dysfunction and those found both in schizophrenia and, to a very considerable extent, in autism. Underlying abnormalities of both structure and function in the right hemisphere have been identified in both conditions. However, given that one of the underlying abnormalities is, precisely, abnormal lateralisation of both structure and function in the brain, it is less certain how to interpret them. Naturally I do not contend that either autism, or schizophrenia, is *merely* a right hemisphere deficit syndrome: it is obviously more complex than that. I think, however, that it cannot be denied that they have, in a host of respects, remarkably comparable phenomenology.

For a number of reasons, we have more extensive and detailed accounts of their experience from subjects with schizophrenia and autism than we do from subjects with right hemisphere injury, stroke or tumour. Western modernity has many overlapping features with the phenomenology of schizophrenia, as Louis Sass has convincingly demonstrated in *Madness and Modernism*; and I submit that this is because modernity simulates not a disease state, but a hemispheric imbalance, as I suggested in *The Master and his Emissary*. The testimony of people with schizophrenia and autism provides us with articulate accounts of what living in the left hemisphere's world feels like, when most fully expressed. Such accounts help to make sense of apparently disparate phenomena around us, and give us a perspective on our unexamined assumptions about the fabric of reality – in one sense, the whole purpose of this book.

CODA TO PART I

What do we learn from all this? The main point in Part I has not been so much to demonstrate the left hemisphere's weakness in this or that area: it has been to demonstrate that the differences are stark in every area relevant to making sense of the world. What I think I have shown in these chapters is that the left hemisphere is, compared with the right hemisphere, unreliable in just about every way that matters. In terms of attention to the world, and its role in thereby constructing, and understanding, experience; in its inability to comprehend time, space and motion; in its lack of skill in conveying and interpreting emotion; in its (lack of a) sense of the body as a living inseparable part of the self; in the comparative weakness of its faculties for direct perception, for the evaluation of beliefs and for making judgments; and indeed in terms of its lesser intelligence (which means understanding): in all of these it is more vulnerable to falsehood, more likely to deceive us, than the right. What it can continue to do on its own is to produce language (while having only a partial grasp of the overall meaning of its utterances and those it receives from others), and to calculate (without necessarily understanding the overall meaning of what it is calculating).

You may well be reflecting that I must have unfairly neglected some aspect of the left hemisphere's *Wahrnehmung*, some aspect of its truth perception: it makes no *sense*, you may reflect, after all, that one entire hemisphere of the brain should be more veridical in almost every respect. In fact, however, the logic works the other way: it would be very odd if it were otherwise. And here's why.

It is not the extent of the difference between the hemispheres that we should be wondering at: it's the fact that there is one at all. After all, the world surrounds us on all sides, and the need to be in touch with it is, *prima facie*, equal for both hemispheres, no less for the left than the right. What is clear, however, is that there is a tendency in the left hemisphere to turn from the business of dealing with experience towards the process of abstraction and representation. As a result, the left hemisphere appears to have difficulty understanding the real world, the one in which we actually live, and move, and have our being. But then comes the realisation: *it doesn't have to*.

It is a little like a high-ranking bureaucrat, protected from the world which he or she must administrate: adept at knowing and observing the rules, but knowing little if anything about life as it is lived there. All that it leaves to the right hemisphere. A reporter on Mao's China wrote:

The original purpose of the so-called May Seventh schools was to allow bureaucrats to be periodically in touch with workers and peasants. In practice, nothing of the kind occurs: one cadre, when I asked him whether he lived with the farmers during the periods when he worked in the fields, was quite shocked by my question. One should know that since the May Seventh schools have been institutionalized, they have become bureaucratic islands in their rural environments. Their inmates plant cabbages and feed pigs, granted, but they do it *with other bureaucrats*, on the school grounds. Do they get any chance to learn about the life of the peasants? Of course! Once or twice a week some farmer comes and gives them a talk, and tells them how Chairman Mao and the Party have changed his existence out of all recognition.¹

The processes are self-referential, internally validating, and self-confirmatory. The serious problem for humanity is that the left hemisphere is prone to see the world this way and to 'go it alone'. Not knowing what it is it doesn't know, it tends to be overconfident it is right. This does not happen the other way round because the right hemisphere seems to be aware of its limitations, as well as of shades of meaning and degrees of truth; and it is more in touch with reality, while the left hemisphere prefers its theory about reality: there is an analogy with the effects of what

nowadays we'd call being inside a 'thought bubble'. As I aimed to show in *The Master and his Emissary*, this overconfidence in the left hemisphere point of view on the world has twice before heralded the demise of a civilisation, and I believe it is doing so for the third time as you read these words.

The right hemisphere-damaged subject, overly committed to the left hemisphere mode of simply putting together the pieces, joining the dots, and following procedures, is unable to appreciate that the picture he arrives at is bizarre and incoherent. He placidly accepts the preposterous nature of his conclusions, and, if things seem improbable or awry, he no longer feels the strange or surprising nature of them. They fail comprehensively to alert him, in the way that they normally should, that there is an aberration. In this he is like schizophrenic subjects, who adopt what Sass & Byrom call an 'anything goes' orientation, in which they 'quickly identify, accept and take in stride phenomena that most people would find anomalous, strange to the point of being difficult to recognize'.²

In a study by Howard Gardner's team as far back as 1981, after detailing the performance of the right hemisphere-damaged subject, the authors comment: 'It is as if the left hemisphere is a highly efficient, but narrowly programmed linguistic computer.'³

Indeed. The brain is often compared to a computer. This metaphor is one of the scourges of our time. The brain is nothing like a computer, nor does human memory have 'data banks' like a computer's. There is, however, just one respect in which the left hemisphere of the brain does function a little like the *brain's own* private computer: it is largely an intermediate processor. It is not a computer, with *no* contact with reality, *no* insight into what it is dealing with and relying heavily on routine procedures; but, compared with the right, it begins to look like that, and it does so more convincingly than any other aspect of brain functioning. As an intermediary, which is what it seems at best to be, contact with reality comes before and after the left hemisphere processing. Material from the real world as presencing to the right hemisphere is fed into a largely closed system, that of the left hemisphere, with its own rules and procedures, and then emerges to be reinterpreted in the real world once more, by the right hemisphere. Michael Gazzaniga's observation about what he calls the left hemisphere interpreter is spot on: 'that the interpreter is only as good as the data it receives is crucial in explaining many seemingly inexplicable

behaviours, of both normal brains and neurological patients. Indeed, if you feed the interpreter incorrect data you can hijack it. ... So perhaps, for our interpreter [the left hemisphere] process, reality is virtual.'⁴ That takes the words out of my mouth.

I demonstrated the evidence that perception in all modalities is attenuated in the human left hemisphere compared with the right. In the pre-human cerebral cortex, however, the left hemisphere is less *conceptual*, more *perceptual*. In monkeys and apes, for example, visuo-spatial skills are less lateralised, with more remaining in the left hemisphere than is the case in humans, where that territory has been colonised by abstractions.⁵ And, as if to confirm this, in some human individuals we can actually see a possible relic of the past: such subjects retain vestiges of visuo-spatial skills in the 'language' areas (for which, read 'concept-forming' areas) of the left hemisphere.⁶ As is often the case, ontogeny recapitulates phylogeny; that is, we can see a microcosm of the history of the species in the history of the individual (eg, human embryos have tails which they lose as gestation advances). Thus colour recognition, *including* the categorisation of colours, is right hemispheric in infants, but the *categories* of colour perception become left hemispheric in adults: 'as you learn the words for colour, as your categories become more linguistic, they become more left-hemisphere dominant', suggests one study's author.⁷ The trend has been for the left hemisphere to shift from perception to conception, from experience to abstraction, from life to language. If it has achieved that well, it will be not *patchily* less veridical than the right hemisphere, but consistently so across the board. And that is what we find.

It may be that the advent of language alone produces, and indeed requires, this distancing from reality, this degree of alienation in one half of the brain. And, as a corollary, it may be that, while depression, anxiety, obsessive-compulsive disorder and other psychological maladies exist in animals, as far as we know schizophrenia does not.⁸ It has often been surmised that there is likely to be a relationship between language and psychosis. I believe that this is correct. The question is usually pursued at the genetic or microbiological level, which is perfectly valid, and may one day prove positively useful, but is slightly like trying to understand Shakespeare by analysing the keystrokes that are required to type Macbeth. One misses what is going on at the human level.

What I am suggesting is this: in animals there may be no such thing as schizophrenia because, except in humans, both hemispheres still maintain their groundedness in the pre-conceptual world. Because of the ‘virtuality’ that has necessarily followed the left hemisphere’s primary preoccupation with the world of symbols, as far as reality is concerned we have ended with ‘all our eggs in one basket’: the one on the right. As a result we are particularly vulnerable to anything that impairs the right hemisphere, since it is our mainstay in reality.

Referring to the loss of power in the left hemisphere to make intelligent perceptions, Michael Gazzaniga writes:

That a lowly mouse can perceive perceptual groupings, whereas a human’s left hemisphere cannot, suggests that a capacity has been lost. Could it be that the emergence of a human capacity like language – or an interpretive mechanism – chased this perceptual skill out of the left brain? We think so...⁹

And so do I. The left hemisphere’s world is now an increasingly *virtual* world. It no longer even pretends to yield a faithful portrayal of reality. For that it depends on the right hemisphere. It has, it thinks, more important – certainly other – things to do. It is there to unpack the implicit in what it is given about the outside world, make it explicit and deal with it according to the rules. It is there to aid strategy. Unfortunately, by being purely strategic in intent, the left hemisphere makes strategic mistakes, since it remains largely ignorant of the reality on which it relies. As a sophisticated computer would. And very soon, no doubt, will.

I was very struck on re-reading Oliver Sacks’s *The Man Who Mistook His Wife for a Hat* after 30 years to come across this passage, germane in so many ways to our discussions:

The entire history of neurology and neuropsychology can be seen as a history of the investigation of the left hemisphere ... it is the right hemisphere which controls the crucial powers of recognising reality which every living creature must have in order to survive. The left hemisphere, like a computer tacked onto the basic creatural brain, is

designed for programmes and schematics; and classical neurology was more concerned with schematics than with reality.¹⁰

As Sacks points out, though right and left hemisphere strokes are equally common, one can find ‘a thousand descriptions’ of syndromes following left hemisphere stroke for every one description of a right hemisphere syndrome. He comments: ‘It is as if such syndromes are somehow alien to the whole temper of neurology...’

In Part I of this book we have seen quite how extraordinary, and how extraordinarily revealing, these right hemisphere deficit syndromes are: how much *more* important they are than left hemisphere deficit syndromes for human meaning.

There are two related consequences of such a state of affairs that appear diametrically opposite but, as so often, for that reason are closer than we are normally willing to accept. They are the coming together of unreasonable gullibility with unreasonable scepticism. The left hemisphere is both unreasonably willing to jump to conclusions (and stick to them), and inclined unreasonably to put in doubt the basics of existence. While it is extraordinarily credulous (believing that a paralysed arm functions normally), it will simultaneously exhibit doubt as to the most basic foundations of reality – believing that people are really all involved in a play-acting conspiracy, that their continuing corporeal being is an illusion, that they are not conscious but really machines, and so forth. This is entirely to be predicted. When you are out of touch with reality you will easily embrace a delusion, and equally put in doubt the most basic elements of existence. If this reminds you of the mindset of the present day materialist science and philosophy establishments, as well as of the loudest voices in the socio-political debate, we should not be particularly surprised, since they show all the signs of attending with the left hemisphere alone. I live in the hope that that may soon change: for without a change we are lost.

In *The Master and his Emissary* I explored the history of how this has come about, and how our world might be experienced if the left hemisphere were, finally, fully to subordinate the right hemisphere in the process. It is a frightening vision but one which to me and to many others is already familiar in the world around us. Many readers who share my deep alarm at the world we are creating asked the obvious question: ‘So, what’s the solution?’ Some may have hoped for a five-point plan, but of course there

isn't one. We need to address the problem at a much more fundamental level.

We need to look at the roots of the malaise. We need to do nothing less than reconceive our world, our reality in a way that, far from subordinating the right hemisphere, acknowledges that it alone has access to the world beyond us, 'out there'. We need to learn again to look, to see. That's to say, we need to redirect our attention to *what-out-there-is-not-us* in a way that rebalances the contributions of the two hemispheres so as to bring a world into being that is truer, richer and within which we can live less harmfully, more peacefully and with much greater fulfilment. How we might do that is the purpose of the rest of this book.

In Part II I want to explore what rebalancing the contributions of the hemispheres would entail for the paths that are available to us to follow in attempting to understand the truth about the world – paths that are of course themselves shaped and directed by the functioning of the hemispheres. Then, in Part III, I want to look at some of the key elements in that reconceived world as it comes into being when the more veridical hemisphere, the right hemisphere, is not subordinated to the left hemisphere, but is able to reassert its role as master to the left hemisphere's servant. It will become apparent how radically we have come to misconceive so much that we 'take as read'. And we shall see how very different the world is from the one we think we know.

PART II

The Hemispheres & the Paths to Truth

A philosophic outlook is the very foundation
of thought and of life. The sort of ideas we attend to, and
the sort of ideas which we push into the negligible background,
govern our hopes, our fears, our control of behaviour.

As we think, we live. This is why the assemblage
of philosophic ideas is more than a specialist study.
It moulds our type of civilization.

ALFRED NORTH WHITEHEAD¹

'True philosophy entails learning to see the world anew.

— MAURICE MERLEAU-PONTY²

¹ Whitehead 1938 (87).

² Merleau-Ponty 1945 (LXXV).

WHAT IS TRUTH?

Truth is a noun only to God; to men, truth is really best known as an adverb, ‘truly’.

—Rabbi Jacob Agus [1](#)

IN PART II, I WANT TO MOVE BEYOND CONSIDERATION OF THE DIFFERENT *means* made available by each hemisphere, to a consideration of the different *paths* human beings have adopted, in their approach to a truer understanding of the world we inhabit. I take it that these can be encompassed under the very broad, and to some extent overlapping, headings of science, reason, intuition and imagination. In the case of each path I will examine its claims to lead us towards truth, particularly in the light of what we know about the hemispheres.

In these times especially, truth is a pressing question for all of us; it is not enough to leave it to academic philosophers only. That’s in part because our beliefs about it not only help make the world what it is, but make *us* who we are.

No single overarching theory of truth can encompass everything we would wish from such a theory, and indeed truth is never finally known; but that does not in any way invalidate the attempt. We can at least point to what is unlikely to be the case, and indicate a more reasonable path to pursue. And if our aim is to take a new look at what we mean by reality through the lens of the hemispheres, we must begin with the nature of truth;

for each hemisphere is likely to have a different approach to truth itself, as to everything else.

That does not, however, entail that each idea of truth is equally valid. Indeed, one of the conclusions of this chapter, and ultimately of this book, is that one hemisphere's idea of truth is likely to be more fruitful than the other's. As we have seen in Part I, the aspect of reality revealed by the left hemisphere must be contextualised by being taken up into the broader, and deeper, overarching vision available to the right hemisphere; alas, when the left hemisphere takes the lead, it leads us astray. As always, it is a good servant but a poor master.

But if reality is always mediated by the two hemispheres, how can one decide which is more veridical? It has even been put to me that one would need a third hemisphere, so to speak, to decide. This is a lovely idea, but of course why stop there? How would one decide that the third had got there, unless there were a fourth, and a fifth, and so on? But this is to make a basic mistake.

I believe that, despite our always contributing to the reality we experience, there is *something* apart from ourselves to which we *can* be true – that reality, in other words, is not purely *made up by the brain*. There is a relationship there – something to be *true to*. Assuming there is something there to know implies that some understandings will inevitably be better than others. And since each hemisphere provides a different understanding of it, it is perfectly coherent – and indeed necessary – to ask which is superior. (The validity of the question is not affected by the observation that we can, and may be best to, use both.) If a pilot is flying blind and has two navigation systems to rely on, each of which, though they differ, provides significant information, the criterion for having to prefer one over the other is clear: following which one is less likely to lead to a crash. Or again, as a piece of music cannot be experienced without a player, who inflects what it is that we hear, there is nonetheless such a thing as a better or worse performance, one that is more or less faithful to the potential enshrined in the piece – a potential that *is*, essentially, the piece of music, and becomes realised in every true performance. The arbiter, then, in either case, is the experience of the whole embodied person as he or she responds to a more, or less, accurate – a richer, or poorer – account of the world.

Furthermore, if one such account, rendering or assessment was better able, at the same time, to incorporate the best of what was seen by its

counterpart, we should clearly prefer the one that saw the bigger, and better integrated, picture.

What would clearly be crazy would be to use the poorer system only: to admit only the poorer performance. That's the point at issue here. Because our current condition in the modern world, I suggest, is the consequence of doing just that.

EXPERIENCE: PRESENCING VS RE-PRESENTATION

The single most profound difference between the hemispheres, which I will have cause to return to repeatedly, is the distinction between the experience of something as it ‘presences’ to us in the right hemisphere, and as it is ‘re-presented’ to us in the left. Just because we so rarely deal with the world nowadays except as it is represented, and because we are used to mistaking the representation for the thing itself, the full significance of this may not be apparent. Yet as our awareness moves from one to the other, an extraordinary transformation takes place, like moving from a photo album into the living space that was photographed. The two are not necessarily in conflict, but neither are they at all the same kind of experience.

The word ‘presences’ is important, but sounds unnatural. Unfortunately we don’t have an available everyday term, or I’d use it. This in turn is fascinating: why don’t we have a verb to describe the experience of an encounter with reality that strikes us at once as of fundamental importance? The experience not being part of the left hemisphere’s repertoire, language has side-lined it. To ‘presence’ is not the same as to ‘be present’, which is too finished and inert, leaving little place for whatever is there to play an active part in the encounter; or, worse, to ‘be presented’, which is passive, and gets dangerously near to ‘being re-presented’. The shift from the noun (‘presence’) to the verb form (‘to presence’) signals a shift from a passive state to an active process, from a thing to a dynamic, two-way relationship. Historically English-speaking philosophers have adopted the verb ‘to presence’ as a way of translating Heidegger’s use of *anwesen* – though he, too, had to re-invent the verb from what, by his time, existed only as a noun. What I believe he meant by this word is something like to ‘reveal or disclose itself to us’, to ‘come into being for us’, with all the vital, pre-conceptual, active freshness that that suggests.

The whole of Merleau-Ponty’s philosophy of embodied understanding depends, in one way or another, on a fundamental distinction: that between two modes of encountering the world, which he calls ‘*je pense*’ and ‘*je peux*’.² The first deals with a mental representation in which we are quite separate from the world, and the question is, then, how our thoughts can be said to relate to that world; the second is an intuitive embodied awareness

of the world in which we are already fully situated, a field of potential for interaction, something that comes prior to any conscious re-presentation. I believe he was articulating the intuited difference – as have many philosophers, including Bergson, Peirce, James, Heidegger, Scheler, Sartre and Wittgenstein – between the world as understood by the left and right hemisphere, respectively.

Presencing is what the world does less of as we grow older. Wordsworth, the power of whose poetry is, precisely, that it causes the world to presence to us once more, famously lamented that ‘shades of the prison-house begin to close upon the growing boy’.³ The effect is accentuated in an era where so much of our experience comes already conceptualised in such a way that we are shielded from its awe-inspiring reality. So often now it comes in virtual form, second-hand, and pre-digested. Though she was writing more than a hundred years ago, Evelyn Underhill already saw the troubling modern submission to the world of representation, and expressed it, I think, brilliantly:

It is notorious that the operations of the average human consciousness unite the self, not with things as they really are, but with images, notions, and aspects of things. The verb ‘to be’, which he uses so lightly, does not truly apply to any of the objects amongst which the practical man supposes himself to dwell. For him, *the hare of Reality is always ready-jugged*:⁴ he conceives not the living, lovely, wild, swift-moving creature which has been sacrificed in order that he may be fed on the deplorable dish which he calls ‘things as they really are’. So complete, indeed, is the separation of his consciousness from the facts of being, that he feels no sense of loss. He is happy enough ‘understanding’, garnishing, assimilating the carcass from which the principle of life and growth has been ejected.⁵

One example of this process in action, and one which has already been, and will continue to be, important for the argument of this book, concerns our relation to space and time. The process of re-presentation, of (literally) striving to make something present again as it were ‘after the event’, ignores the significance of time. This is already a considerable step away

from reality. When we think about time, only a massive effort of will can prevent us substituting a one-dimensional representation – time as a line in space – for the full experience that is understood only through our embodied intercourse with the world as it *presences*. Space, too, is reduced to the world's two-dimensional representation – as if projected on a screen. We are so used to giving in to this virtualising and distorting process that we don't even notice that we are doing it. Since space and time are where we live, that is a pretty important fact: I will have much more to say about that in Part III of the book.

If the hemispheres generate different worlds, one that broadly presences and one that is effectively represented, this has consequences for the attempt to make sense of the world, otherwise known as philosophy.

TRUTH: AS A THING OR AS A PROCESS?

From everything we know about the hemispheres, we would expect that, in the left hemisphere's world, truth would be conceived as a thing, rather than a process. (It might be abstract – indeed it would have to be abstract, since that is how the left hemisphere deals with the world – but it would still be the abstraction of a thing.)

Truth, this thing, would be conceived of as existing in the realm of subjectivity (in the mind) as a suitable representation of something conceived of as existing in a realm of objectivity (outside the mind). From this point of view, the way to approach truth would be to start with a secure set of facts, and then work upwards by rules of logic, to a series of other facts, putting one secured item on top of another, to build the pyramid of (represented) truth. In principle, this truth would be impersonal, something that could be transmitted, as it stands, directly to another; timeless and unchanging – and independent therefore of context; ultimately single, in that if the path is rigorously followed, everyone should reach the same conclusion; and ultimately perfect, precise and certain – theoretically attainable goals that are *not yet* achieved, so the argument would go, only because we have not yet concluded our deliberations.

Note the words 'representation', 'fact', 'perfect', 'precise', 'certain', 'concluded'. What do these words have in common?

They all suggest a process that has now stopped. Something that *was*. Motion, time, flow are replaced by stasis, eternity and fixity. Look at the lineage of the words. (I accept, of course, that words change their meaning over time. However, through etymology they disclose to us the patterns of thought that lie at the foundations of our culture and are built into the history of our ideas. As familiar, by now – and as invisible – as the air we breathe, we no longer recognise them for what they are.)

All these words come from Latin roots:

- *Representation* speaks for itself. The word *present* comes from the present participle *præsens* of *præ-esse*, meaning 'to be there in front of' (the speaker). *Re-presentation*, then, is the attempt to

make something appear ‘in front of’ the subject *again*, after the fact: something that is by definition no longer actually there.

- *Fact* is from *factus*, past participle of the verb *facere* ‘to do’ or ‘to make’, and it means a ‘something that has been done (or made)’ – and is now in the past, and no longer there.
- *Perfect* is from *per-fectus*, another past participle of a similar root, *per-facere*, by adding the prefix *per-*, meaning ‘through’: to do (or make) completely or thoroughly (or, as we used to say, ‘thoroughly’) – thus what is perfect is ‘that which has been done through to completion’.
- *Precise*, as mentioned, is from *præ-*, before, + *cisus*, cut, past participle of *præ-cidere*: literally ‘having been cut off before its time’.
- *Certain* comes from *certus*, originally the past participle of *cernere*, to decide or determine; ‘something that has been determined’.
- And *concluded* is from *con-*[intensifier], + *claudere*, to shut – to ‘shut off’ or ‘lock up’ completely.

My point is not a narrowly grammatical one, that they mainly derive from past tense formations – after all, even the word ‘process’ comes from a Latin past participle. My point is, rather, the intrinsically completed nature of the idea in every case, which the grammar naturally reflects. A ‘process’ is not generally completed at the moment it is alluded to, but is temporally open: it may be continuous, and ever more coming into being. A ‘fact’ is, however, intrinsically finished, or ‘established’, as we say – which means standing firm (cf ‘stable’), unmoving, where it is. A fact is a thing, not a process.

While this view of the world, which characterises the left hemisphere, allows for the possibility of change, that change has to be accomplished by a series of, in themselves static, steps – not a flow. It is the substitution of one, in principle, fixed, static ‘fact’ by another, like the succession of static stills that produce the effect of motion in a ciné film – until the final ‘facts’ are reached. And then the film ends.

So, how would the right hemisphere conceive truth? Rather than conceiving it as a thing, it would experience it as a process, one that, in this case – not just for now, but in principle – has no ending. More importantly,

it would see that truth is a *relationship*. Instead of seeing a subjective realm and an objective realm which should as near as possible mirror one another, it would see a constant *reverberation* between two (never completely distinct) elements within our consciousness – thoughts and experiences – whereby they ‘*answered*’, or co-responded to, one another; this ever better *accord*, or *attunement*, would *be* the evolving truth. It would be intrinsically incomplete, but constantly in the process of completing itself; and uncertain, though constantly approaching nearer to certainty; incapable of being grasped except through embodied being, through a consciousness that is in the flesh and *engaged* in the world. We would find out what was true only by testing it on the pulse of experience – whether it corresponded with the totality of our experience, not just with one (cognitive) part of it. Because of this it would be unique and necessarily many-stranded.

Please note, nothing about this right hemisphere view suggests that the pursuit of truth becomes pointless – on the contrary, it is demanded. This is not an invitation to give up on something difficult: rather it summons a disciplined attentiveness and an open and active receptivity to the task. Agreement, common ground, can still be, and needs to be, reached, because experience of the world is not random. Truth is emphatically not a free-for-all, a matter of individual whim. Many things – most of the really important things in our lives – can never be proved, but are nonetheless far from being a matter of ‘anything goes’. Here Ricoeur comes to mind:

If it is true that there is always more than one way of construing a text, it is not true that all interpretations are equal ... The text is a limited field of possible constructions. The logic of validation allows us to move between the two limits of dogmatism and scepticism. It is always possible to argue for or against an interpretation, to confront interpretations, to arbitrate between them, and to seek for an agreement, even if this agreement remains beyond our reach.⁶

We cannot force an opinion about what is good or beautiful on someone who is not prepared to accept it. Yet, as Edmund Burke noted, there is more likelihood of agreement in such judgments than in reasoned argument:

There is rather less difference upon matters of taste among mankind, than upon most of those which depend upon the naked reason ... men are far better agreed on the excellence of a description in Virgil, than on the truth or falsehood of a theory of Aristotle.⁷

Returning to my description of how the right hemisphere might conceive truth, note the words: ‘reverberation’, ‘answer’, ‘accord’, ‘attunement’, ‘engagement’. In contrast to what we saw earlier, they involve motion, reciprocity, energy.

- *Reverberation* comes from Latin *re-*, again, + *verberare*, to beat, meaning ‘the return of a beat’.
- *Answer* comes from Teutonic roots *and*, + *swara*, and means affirming (as in ‘swearing’) something in *reply* (the force of the old Teutonic word, *and*).
- *Accord* comes from Latin *con-cordare*, from *cor*, the heart: literally ‘to bring heart to heart’.
- *Attunement* means to bring the tune or ‘tone’ of one thing towards (*ad*+) another – the word ‘tone’ itself coming from Latin *tonus*, a ‘stretching, or tension’.
- *Engagement* means a ‘pledge’ or sworn agreement (as in what comes before marriage), from Old French *gage*, something of value given in exchange for action (in its Teutonic form, it is related to the word ‘wed’).

And that leads one to the meaning of the word *truth* itself.

We now tend to think of truth as a matter of propositions. The word ‘truth’ in its origin indicates not a proposition, but a disposition. ‘True’ (cf German *treu*, faithful) is related to ‘trust,’ and is fundamentally a matter of what one believes to be the case. Truth and trust (belief) go together. One cannot have trust in a society where there is no truth; and one cannot be true to a society in which there is no trust. That is of fundamental importance, since, as Confucius told his disciple Tzu-kung, for a stable society a ruler needs three things: weapons, food and trust. If he cannot hold all three, he should forgo weapons first, and food next; for ‘without trust we cannot stand’.⁸

The Latin word *verum* (true) is cognate with a Sanskrit word meaning to choose or believe: like one's loved one, the one in whom one chooses to believe and place one's trust, to whom one is 'true'. We used to speak of plighting one's 'troth' (an older form of the word 'truth'). And we still speak of two surfaces that 'marry' well as being 'true'. They meet and therefore are 'meet'; they fit and therefore are 'fit'. It is a matter of fit – and fidelity.

Belief too is about fidelity (Latin *fides*, faith). The word 'belief' has nowhere buried in it the idea of signing up to a proposition, certain or uncertain. It is not a matter of cognition, but of recognition. The word belief comes from the same root as the word 'love', a sense preserved in the now archaic word 'lief', familiar to us from Shakespeare, with which one once described one's friend, sweetheart, or lord – someone in whom one believed. Similar considerations apply to the German *glauben* (related to *lieben*, to love), and to the French *croire* and other derivatives of Latin *credere*, a word which meant originally to 'entrust to the care of' (the sense lingers, in reduced fashion, in the idea of 'credit'), and originally to 'give your heart to' (possibly from Latin *cor do*; certainly involving Proto-Indo-European root *kerd*, heart). Belief is about a relationship, in which by definition, more than one party is involved. The believer needs to be disposed to love, but the believed-in needs to inspire another's belief or trust. Whether this amounts to being worthy of that belief cannot be fully determined in advance. It emerges only through commitment and experience.

Etymology is hugely revealing. Slippages in meaning tell us about the direction in which we may have drifted without even being aware of the drift, much as rifts in the bedrock speak to us of continental drifts that made the landscape in which we live, but which we cannot perceive. The left hemisphere regards words as tokens that can be manipulated to mean what we like, not living, embodied signs, with a history. That way danger lies: so-called 'post-truth' being one. I repeat, I am not trying to rewrite the meaning of words, but precisely the opposite: in an age when language has become deracinated (which literally means, like a flower uprooted) from its embeddedness in a community of human beings, I am merely showing how we have got where we are now. History is always relevant, because life is not a series of moments, but a continuous flow. One of the most ignorant remarks ever made, representing the machine world view for which we are

now paying, and will continue to pay, a very high price, is Henry Ford's 'history is bunk'.

Be that as it may, I think it possible that some of the disagreements in the debate about truth start with these broad differences in whether we see 'truth-as-correctness', a thing that can be determined, and into which nothing of us enters; or 'truth-as-unconcealing', a process of something revealing itself to us only through our experience. (Heidegger often used the Greek word for truth, *aletheia*, which literally means 'un-forgetting', allowing something to emerge from oblivion.)

How do we decide which way of conceiving truth is truer?

First, notice that a process, unlike a thing, suggests the importance of not just the whatness, but the howness. There are no deep truths that are separate from the manner in which they are expressed. As the philosopher Friedrich Waismann puts it:

If you ever try to put some rare and subtle experience, or a half forgotten impression, into words, you'll find that truth is intrinsically tied up with the style of your expression: it needs no less than a poet to render fully and faithfully such fragile states of mind.⁹

Which is why we honour poetry as a path to truth. As I will argue, the most fundamental truths, of both a physical and psychical nature, can ultimately be expressed only in terms of poetry. And Waismann points out that the meaning of the word *truth* differs with context, so that it has 'a *systematic ambiguity*', as have deceptively simple sounding words such as *fact*, *statement*, *knowledge*, *law* and many others.¹⁰

WHO CORRESPONDS WITH WHAT?

There are a number of conventional ‘families’ of approach to truth. I can’t pretend to do justice to the subtle disputations on this theme that have occupied some of the cleverest minds in history (some such disputations, nonetheless, especially in the last century, being more notable for the heat, than the light, they generated, at least in my view). What I offer in the rest of this short chapter are some elementary reflections on the main ways in which truth has been regarded, the bare minimum necessary to act as an introduction to the next few chapters, in which I will discuss the possible *paths to truth*.

The idea of truth always implies *some* sort of correspondence. One major strand in thinking over the centuries is, indeed, known as ‘correspondence theory’: that truth lies in a correspondence between what goes on in our minds and a mind-independent reality. The closer the two come, the more we can speak of truth. According to such a view, understanding is the forging of links between symbols in the mind and that reality, such that it is accurately represented internally. This is intuitively appealing. But, since according to this view we have no direct contact with reality, and we cannot know anything except as we know it, how, according to this view, could we know whether our knowledge is true to what is ‘out there’, before the very fact of our knowledge of it has been substituted for it? Is there, in fact, such a thing as a world that just simply is ‘out there’ – wholly mind-independent – at all? Does this not already set up the left hemisphere’s idea that all we experience is a re-presentation?

The classical counterpoint to correspondence theory is ‘coherence theory’: that truth lies in the cohesion of what it is that goes on in our minds. If something coheres with – and, moreover, mutually sustains – other things that we hold to be true, it may be regarded as itself true. Otherwise it is false. Here there is still a correspondence, but it is not between what ‘goes on in here’ and what ‘goes on out there’, but between the elements that ‘go on in here’.

Coherence also has an intuitive appeal, but has its own problems. A whole set of beliefs could be mutually coherent and entirely false: everything depends on where you start from. How are we to judge the best

place to start? If we believe the world is flat, we can hold a myriad of ideas that are coherent with that – but wrong. What's more, why do we suppose that truths may not conflict? Opposites may both be true. It's possible, I agree, to have amongst your beliefs an overarching belief that contradictory statements may both be true, but this seriously undermines the usefulness of coherence as a criterion of truth.

As the philosopher Anthony Quinton pointed out, a solution that involved the 'close interweaving of the correspondence and coherence theories' would be progress, and would 'explain why the conflict between them has continued for so long'.¹¹ I will discuss shortly, a way in which I believe something like this hoped for rapprochement can be realised.

There exist, naturally, further possibilities. 'Consensus' theory holds that what is true is what is generally accepted to be the case. The correspondence here is between the views of different individuals. This is beguiling, but hardly convincing. For one thing, if people generally held consensus theory to be false, and many people do, it would be a non-starter, because it would be itself untrue. Leaving that aside, how would one determine in practice the outcome of a potentially infinite series of referenda? Moreover, fairly obviously, the majority can be mistaken: the world is not flat, though at one time the majority may have thought it to be so. And how could any new truths be discoverable? At the outset almost everyone would consider them false – and they would therefore have to *be* false.

There are a number of 'deflationist' – or in my view, more accurately, defeatist – versions of truth. One holds that the whole idea of truth adds nothing to a linguistic assertion that something or other is the case, and should therefore be abandoned. 'Relativist' versions suggest that, since there is no one clear truth, everything being context-dependent, once again the whole idea of truth needs to be abandoned, each of us having our own truth. 'Social constructivism', at least in its strong version, suggests that truth is simply fabricated by society, being in effect what that society holds to be true – an invention that, according to some, is used by a powerful elite to disenfranchise others.

I suggest that both the disappointed hopes for truth here, and the rejections of all hope for truth here, are equally mistaken, and equally based on a belief in truth as a thing: 'truth-as-correctness'. This is what I have suggested is the left hemisphere's path. And we see classic left hemisphere

characteristics: fear of uncertainty, coupled with its black and white ('either/or') manner of conceiving the world, playing an unhelpful role: either truth is certain (at least in principle, even if we never attain it, as in science), or it doesn't exist. Or at any rate, if it does exist, it can't be of any use. Remember the left hemisphere's *raison d'être* is utility in the service of manipulation. If the matter can't be usefully demonstrated in such a way that it compels a conclusion – if it is in other words, no longer *coercive* – it has no use, no 'function'.

It might be pointed out, however, that two thousand years of insistence, in the West, on the idea of truth as single, timeless and correct has demonstrated only how multiple, contingent and fallible it seems to be, since it has notably failed to coerce the wisdom of philosophers to any one point of view. The ambition of being able finally to demonstrate truth to someone incapable of seeing, or determined not to see, what one means is a complete waste of time. Why should truth have a coercive quality?¹² Truth might be more a matter of something to which we are drawn freely as it were 'from in front' – attracted – rather than compelled inevitably 'from behind' – pushed. Very little that we take for granted as most essential to life – love, energy, matter, consciousness – can be convincingly argued about, or even *described*, without becoming ultimately self-referential. You have to experience it to know it: all we can do is point.

Correspondence theory founders on the unworkable idea that we could know what something is like when we are not knowing it. And all the alternatives compel in one way or another the conclusion that we are like prisoners in a cell, with no window giving directly on the world: it is implicitly assumed that, because we can't know a reality without 'our knowing it' entering into the equation, therefore we can't know reality. As a result, what we decide to be true must be determined by our own minds, as we discuss amongst ourselves what reports we have of where we are and what we know. It's just what makes sense linguistically in relation to how we act. If our image hangs together internally, or is generally agreed to be the case, or makes linguistic sense, that's the best we can hope for. And according to the other theorists truth is not a helpful concept anyway and should be abandoned.

STICKING WITH THE CONCEPT OF TRUTH

I wouldn't give up on truth that easily. After all, truth may rarely be pure and never simple, but it sure as hell exists – even if one sign that we were certainly deluded would be certainty that we were in possession of it. Uncertainty here is not a sign of failure, but lies deep in the nature of what we are trying to grasp. Truth is uncertain not because it is *empty*, but because it is *full* – rich, complex, manifold. (This is related to what I believe to be the mistaken assumption that because we cannot pin down the 'meaning' of the world in which we live, it *has* no meaning: I will argue that this experience comes not from there being no meaning, but from there being a plenitude of meaning, beyond simple articulation.) Some postmodernists leap from the uncertainty of truth to its non-existence, but this assertion is open to the obvious rebuttal that it is a truth statement, which asserts that the assertion that 'there is no truth' is truer than its opposite, that 'truth exists'. If we seriously doubted the *existence* of truth, none of us would get out of bed in the morning, because there would be no point in preferring any one course of action to any other. There'd certainly be no point in writing, or reading, a book. No philosopher that ever lived, whatever his professed creed, behaved as if there were no truth.

But why assume that our experience is not what it seems to be, that is to say direct and real? Open to only a small part of reality, of course, but nonetheless real for that. Just because we midwife it into being, and just because we can never see it whole, it doesn't follow that the world we know is a fantasy.

What I propose here combines elements of the thinking of the American Pragmatists (James, Peirce and Dewey) on the one hand and of the European phenomenologists (particularly Merleau-Ponty, Scheler and Heidegger) on the other, but it would be wrong of me to try to annex their names – and their far from mutually agreed ideas – to my simple reflections. I mention it in case someone should think I am not aware of my intellectual debts.

If we place the emphasis on truth as a relationship, which is where we started, rather than as a 'thing', certain aspects become apparent. In a relationship, both parties count, and the relationship isn't a separate 'thing',

but contains both parties that constitute it. It doesn't lie in one or the other alone. This means that it is necessarily lived; changing and contextual. But it is none the less real for that: on the contrary, it is maximally real precisely *because* of that. It is also something deeply rooted in experience. It doesn't matter what the theory dictates, if it doesn't 'answer' in practice. The proof of the pudding is in the eating. So the Pragmatists such as William James believed. 'The benefit of holding true beliefs, according to James, is that if what one believes is true one is, so to speak, guaranteed against recalcitrance on the part of experience', writes the philosopher Susan Haack. 'No doubt one could get along perfectly well, for a bit, holding false beliefs; but, James thinks, one would eventually be caught out.'¹³ Wittgenstein learnt a great deal from William James and his later work is arguably Pragmatist in style.¹⁴ According to one of his pupils, 'Wittgenstein very frequently referred to James in his lectures, even making on one occasion – to everybody's astonishment– a precise reference to a page-number! At one time, furthermore, James's *Principles* was the only philosophical work visible on his bookshelves.'¹⁵

I should say right away that Pragmatism is not the same as being pragmatic, just believing 'whatever works' to be true, because, as long as the context is carefully defined, almost any view can be said to 'work', even if clearly false. Treating people as objects 'works' if your aim is to be as efficient as possible in sending them to the gas chamber. Treating nature as a heap of resource 'works' if your aim is to make plastic as cheaply as you can. Treating a cell as a machine 'works' if your aim is to find a lock and key mechanism for changing its function. But people are not objects, nature is not a heap of resource, and, as I shall later explain, a cell is not a machine. In a less narrow context each of these 'truths' breaks down. Eventually – or rather quickly – we are, as Haack puts it, caught out. These modes of thinking do not truly answer to our experience at all. Thus, while pragmatic, they are not Pragmatist.¹⁶ Pragmatism is a form of open-mindedness that judges ideas not by their roots but by their fruits.¹⁷

We should be used to this idea of truth and falsehood, because we are constantly confronting the fact that the world does *not* confirm our modern Western 'take' on it. It doesn't respond, or correspond, to our fantasies. Yet we behave as though our theories about reality were more important than what experience keeps telling us. This is consonant with our world view being skewed towards that of the left hemisphere. Both hemispheres need to

update what they know of the world in the light of experience, and the right hemisphere tends to make changes to its ‘version’ as it gathers information from experience. The left hemisphere, however, tends to stick to its theory in the face of disconfirming evidence. This has been repeatedly demonstrated.¹⁸

As usual it is not a matter of the right hemisphere versus the left hemisphere in the sense that one must be right and the other wrong, but the need for a judicious harmonising of them both. Each has its place. Nothing needs to be ruled out in the relationship between the hemispheres. But, as always, *they are not symmetrical in value*.

Let me suggest an analogy. Newtonian mechanics is at one level incompatible with quantum mechanics. It does useful work at the level of day-to-day reality, but at the subatomic level, or at the cosmological level, it no longer applies. But it is not that quantum mechanics applies only at the extremes of magnitude, and Newtonian mechanics, which contradicts it, applies only in the bit in the middle where we normally focus. That would be like saying the earth is curved elsewhere, but flat wherever we happen to be. It’s always curved: just for everyday purposes it looks flat, and we don’t need to take the curve into account. Similarly, quantum mechanics applies across the whole field; Newtonian mechanics is just a handy approximation that can be overlaid on quantum mechanics for *practical purposes*, provided it is restricted to the day-to-day level. It won’t help us understand the underlying reality – in fact it misleads us there. But it has its own, prodigious, usefulness.

Note that it is the precision of Newtonian mechanics that makes it a less good fit, while the intrinsically less precise quantum mechanics is more accurate. I am reminded of the way in which template-driven ‘packages of care’, now enjoined as good practice by managers of our healthcare system, are always, despite their crispness, a poor fit to the individual case because general, and precise – whereas the fuzzier, personally tailored response is a much better fit, because individual, and accurate.

A further etymological observation: ‘accurate’ derives from Latin roots *ad-* + *curare*, ‘to exhibit care towards’.

Precision and accuracy are often confused. It is said that a curator at the Natural History Museum was intrigued to hear one of the attendants telling an impressed party of tourists that a dinosaur skeleton was 9 million and 6 years old. When the curator later asked how the attendant knew, he received

the reply: ‘Well, it was 9 million years old when I started working here, and that was six years ago...’ More precise, but less accurate.

Newtonian mechanics is more precise, though less accurate. Our lives would be practically impossible without it. Its contribution is *necessary*. We need its limiting, clarifying logic. Yet it is not of equal status with quantum mechanics when it comes to the disclosure of reality.

So it is with the complementary nature of the contributions of left and right hemispheres: the first is *as necessary as* the second, but not as capable of disclosing reality. Its vision is limited, clear-cut, handy for the everyday. More precise, but less accurate.

Philosophical and cultural disputes often founder on the misunderstanding of opposition (as in this case of the left hemisphere and the right hemisphere). If it is seen as a matter of ‘either/or’, in which one is triumphant and the other destroyed, opposition is misunderstood. But this is already the standpoint of only one hemisphere – the left hemisphere as opposed to the right. Adversaries can both be ‘good’ to and for one another because of their very opposition, which enables each to be more itself, and additionally allows something quite new to arise from their conjunction. In any case, whether we like it or not, they are mutually necessary. Opposites are not to be resolved by eliminating the one we happen to dislike, any more than lopping off the south end of a bar magnet gets rid of the south pole: it just shortens the magnet.

THE 'SUBJECT-OBJECT DIVIDE' AND WHERE THAT LEAVES THE CONCEPT OF OBJECTIVITY

Since this matter of the relation between opposites is going to recur, let me say something of the troublesome subject-object divide, since it is in general relevant to the nature of truth.

A representation is by definition removed from the immediacy of what it re-presents. It thus creates the question, what is the relation between the representation and that which it represents – that which *presences*? This is the left hemisphere's problem, because it is the hemisphere of representation. The hall of mirrors makes the reality of what exists outside that endless circle of reflections problematic. How does the subjective (the world inside the hall of mirrors) relate to the objective (whatever exists outside it)? But this question does not arise for the right hemisphere. What is present to the right hemisphere is just that: *present*, in the very moment of our experience, in our *comprehension* of it, not before, after, or as a consequence of, something 'in here' that now has to be related to something 'out there'. It is a single experience.

It is said that Bashō told a disciple that the problem with most poems was that they were either subjective or objective. The student said, 'You mean too subjective or too objective?' Bashō's reply in full was, 'No'.

Another way to view the problem is to distinguish the right hemisphere's view of what we call opposites from the left hemisphere's view. To see just how misleading the subject-object divide is, one does not need to go to spiritual sages or theoretical physicists, though either would be able to give a much richer and deeper account than the one I can give here. (I will explore their views further in Part III.) For now, let me merely quote one representative passage from Schrödinger:

It is the same elements that go to compose my mind and the world ... The world is given to me only once, not one existing and one perceived. Subject and object are only one. The barrier between them cannot be said to have broken down as a result of recent experience in the physical sciences, for this barrier does not exist.¹⁹

The problem arises because we jump from an awareness of a distinction to the assumption of a division. The poles of a magnet are clearly distinguishable but are not divided; indeed they are interdependent, mutually necessary, ultimately indivisible parts of the same whole. The most immediately concrete way of understanding this non-dichotomy is in human relationships. A good relationship is one in which each party is maximally fulfilled as a differentiated individual, without this in any way detracting from the relationship, but rather being a condition of the possibility of a good relationship at all – and indeed also a consequence of such a relationship. Equally, we are not atomistic, and cannot be ‘ourselves’, whatever that would mean, in a cultural or societal vacuum. Thus a good society is not one in which individuality is lost, but one in which it is fulfilled; yet, at the same time, that individuality must not be a threat to the cohesion of the society. There is such a thing as tyranny of individuals over society, as well as society over individuals.

That may seem a considerable way from any consideration of the objectivist position, but it is not as far as it seems. Take a step closer and look at the development of an individual. What has to be negotiated by every child that matures successfully into a human adult is the separation from his or her early state of fusion with the mother, to one in which he or she is aware of being a distinct person, separate from the mother, yet without the close connexion with her being lost; and, through her, connexion with the rest of the experienced world. This is not a matter of a change of quantity (*more or less* connexion), but a change of quality in the connexion: equally (arguably more) connected, but now in a different way.

We can have no knowledge of the world without our consciousness being part of that knowledge, which means that whatever our knowledge is, it has a lot of us about it, beginning with whatever it is we mean by knowledge, and the ‘having’ of it, at all. Then there are all the preconceptions – and pre-perceptions – that go to constituting what we can know in any one particular instance. According to a position that would be supported by some contemporary physicists as well as philosophers in many traditions, both Eastern and Western, consciousness is, in any case, the primary stuff (at least *a* primary stuff) of the universe, in which case the idea of a realm apart from mind is strictly meaningless; but we do not have to go that far in order to be obliged to accept the point that we can’t hope for ‘objectivity’ in the sense of starting from a blank slate. The alternative

is, however, absolutely not a free-for-all, in which we make up whatever we like and call it truth. If the concept of objectivity is mistaken, the striving for truth that lies behind it is still not only honourable and worthwhile, but absolutely essential.

In practice, if not in theory, we can recognise what is required. It is not the adoption of a dehumanising stare, one which reduces living things to objects. It is not even disengagement, since disengagement radically alters what we can see, and there is no logical reason why what is disclosed to us by disengagement should be preferred to what is disclosed to us only by engagement – though it depends, crucially, on the nature and quality of that engagement. In a famous passage, David Hume writes:

I dine, I play a game of backgammon, I converse, and am merry with my friends; and when after three or four hours' amusement, I would return to these [his philosophical] speculations, they appear so cold, and strained, and ridiculous, that I cannot find in my heart to enter into them any farther.²⁰

The implication is not that his post-prandial view is right or wrong – it is merely different and must lack something (because it misses something that was real enough), even if it gains something (because it now sees something that is also true).

The philosopher Michael Polányi, speaking of the reappraisal of man's place in the universe after Copernicus, writes that we have been enjoined 'resolutely and repeatedly' to abandon our egoistic point of view, and 'see ourselves objectively in the true perspective of time and space'. But 'what precisely does this mean?', he asks.

In a full 'main feature' film, recapitulating faithfully the complete history of the universe, the rise of human beings from the first beginnings of man to the achievements of the twentieth century would flash by in a single second. Alternatively, if we decided to examine the universe objectively in the sense of paying equal attention to portions of equal mass, this would result in a lifelong preoccupation with interstellar dust, relieved only at brief intervals by a survey of incandescent masses of hydrogen – not in a thousand

million lifetimes would the turn come to give man even a second's notice. It goes without saying that no one – scientists included – looks at the universe in this way, whatever lip-service is given to 'objectivity'. Nor should this surprise us. For, as human beings, we must inevitably see the universe from a centre lying within ourselves and speak about it in terms of a human language shaped by the exigencies of human intercourse. Any attempt rigorously to eliminate our human perspective from our picture of the world must lead to absurdity.²¹

All the same, we could make an imaginative attempt to stand aside from our usual viewpoint. Indeed, one of the crucial functions of the imagination is to enable us to take various perspectives on the world: it enables us to 'see how it looks from over there'. This encourages a certain humility about how it looks from one's own perspective, and yet at the same time provides some reason for confidence in what one takes to be the case. Without imagination there can be no objectivity.

Well, I will need to return to this question in different forms at different points in the book.

OPPOSITION: 'EITHER/OR' AND/OR 'BOTH/AND'

Returning to the problem of the misconception of the relationship of the hemispheres as oppositional, this is as simple as whether one takes a left hemisphere, or right hemisphere, view of opposition: one point of view, that of the primarily analytic left hemisphere, is exclusive ('either/or'), while the other, that of the primarily synthetic right hemisphere, is inclusive ('both/and'). Since this is their disposition in general, it also applies to their relationship in particular. To recall the primary myth of the Master (RH) and his emissary (LH), the Master knows he needs the emissary, while the emissary does not know that he needs the Master. The tendency is for the one that sees less (the emissary) to believe that he sees all, while the one that sees more (the Master) sees there are things he doesn't know; just as those who think they know it all know less than those who know they do not.²² To the extent that there is a 'war' here, it is of the left hemisphere's making, and stems from its unwarranted self-belief.

The philosopher James Carse makes a distinction that is relevant to understanding the difference between the viewpoints of the two hemispheres. 'There are at least two kinds of games', he writes. 'One could be called finite, the other infinite. A finite game is played for the purpose of winning, an infinite game for the purpose of continuing the play.'²³ The first emphasises an outcome that closes down the process. The second emphasises the process, which *is itself* the desired outcome.

One of the hemispheric approaches, that of the left hemisphere, aims to close down on truth. The game lasts, while it does so, only because the longed for close-down has not yet happened. Once it has, the game is over.

The other, that of the right hemisphere, aims to open up to truth, and sees the truth as a never-finished seeking after, and evolving of, something that is disclosed *by the very process*, which the 'game' of life continues.

So it is that one mode of truth is first formulated theoretically, abstractly, conceptually; and then tested, if at all, only afterwards. Meanwhile the other is constantly tested during its formulation – in the process of becoming truth. One is like planning out a journey on the kitchen table in advance; the other like feeling one's way – testing or tasting, through touch and tact – forwards on the journey. It is wise not to do

without either approach, though if you have to forsake one, the first, never the second, is the one to let go.

We each of us know only our experience, of course, so there is no reason to believe that there should be a way of making truth coercive. What does my experience tell me? That I am strongly seduced by the assurances of the left hemisphere. They appeal to my desire to know, at last – to be *sure*: to construct an argument, to feel confident that I can persuade people that I have something worthwhile to say; to use argumentation to reach, finally, a conclusion. Yet I am also aware that this approach, important as it is, lacks something, when contrasted with what the living of a life tells me. Truth is an encounter: it needs to be ‘felt in the blood and felt along the heart’, in Wordsworth’s famous phrase. But – this is the crucial point – although it can never be demonstrated in such a way as to coerce consent, consent is nonetheless not only possible, but likely, as long as people are being honest with themselves. The problem as always comes from an attempt to be rigid, a left hemisphere demand that inevitably distorts a reality that is in no respect rigid. We can’t have correctness, we can only have a maximally attentive, maximally open, testing out of our ideas on the world as we experience it.

Thus, when one speaks truth, one hopes that people will agree, but they can always find reasons not to agree if they are determined enough not to hear. ‘That’s just your opinion’, people say, with the implication that ‘my opinion is as good as yours’. And, undoubtedly, it may be – or it may not. That is the point: there *is* still a structure of better and worse, even where better or worse cannot be finally demonstrated so as to avoid dissent. We have become accustomed, in our Western way, to see all exchange of ideas as a kind of battleground in which there will be conquest and defeat. In the East, ancient truths have not commonly been thought such that they can convince (the word comes from Latin *vincere*, to conquer) through argument, but rather that they become appreciated (the word comes from Latin *pretium*, value) through a patient, disciplined opening up of the self to experience. Jan Zwicky puts it like this:

Truth is the asymptotic limit of sensitive attempts to be responsible to our actual experience of the world ... ‘sensitive attempts to be responsible’ means truth is the result of *attention*. (As opposed to inspection.) Of looking informed by love. Of really looking.²⁴

Attention, once again, is the key to what we find; and note that Zwicky refers to a particular kind of attention, looking that is informed by love. Therefore informed by a positive engagement and regard, not by trying to experience it in as far as possible a 'non-experiential' way.

I readily accept that there is no cast-iron certainty here, but there isn't any *anywhere*. So let's get over it. There are, however, degrees of truth, some of them very great, and carrying increasing conviction with experience. Though truth is always my personal judgment, it is not just possible, but necessary, that my judgment should take into account yours and many others. It is far from random, but is, rather, informed by experiment, perception, reason, intuition and imagination. That doesn't make it less reliable than being informed by a single source, such as reason, might have done, but more reliable. Acquiring a degree of judgment that can make these elements intelligently cohere is – or used to be – the whole purpose of education. It is why we study the humanities. What history and classics and literature tell us is not to be found in the sciences anywhere. Nowadays we seem to have forgotten this crucial insight, on which the future of our civilisation nonetheless hangs. Judgment used to be the foundation of the idea of reasonableness – a concept you may remember, but which we are in danger of losing, if we have not already done so, in a mechanised, bureaucratic society. The popular reaction to this has been only to intensify the mechanistic vision: no longer seeing complex, unique individuals but only representatives of groups, no longer open to appropriately nuanced, but simple 'I'm right, you're wrong' positions, and shouting more and more loudly. Reasonableness is as far from unbridled emotion as it is from rote rationality, on the worst excesses of which it acts as a much-needed brake.

PORCUPINES AND MONKEYS

As to which model of truth seems more truthful, the best guide will be experience. But are there any grounds, purely in the neuroscience of hemisphere difference, that could help guide our choice? I think there are. In Part I we have already seen that the right hemisphere ‘sees’ and understands more.

These days I am often reminded of a story by Yuri Tynyanov, called *Lieutenant Kizhe*, published in the Soviet Union in 1927. It concerns a mis-transcription of a record in the Tsarist army, whereby someone mistakenly adds a redundant syllable (*zhe*) to the end of the word *poruchiki* (lieutenants), and in doing so creates a ‘Poruchik Kizhe’, a Lieutenant Kizhe – who doesn’t exist. Despite this handicap, Kizhe pursues a distinguished career: he is promoted through the ranks, where he is known for his dependability, marries, fathers a child, is decorated for bravery and is finally promoted by the Tsar to the rank of General. When the Tsar asks to meet this human paragon, Kizhe mysteriously cannot be found. The Tsar, informed that he is dead, is overcome with emotion, and orders the good soldier Kizhe a state funeral. Meanwhile one Lieutenant Sinyukhaev, who was left off the records by mistake, cannot convince anyone that, contrary to report, he is very much alive, and is forced to wander the highways of Russia, relying on the charity of strangers.

This is, of course, a thinly veiled satire on life in Soviet Russia – amusing, you might think, but far-fetched. However, as has often been noted by satirists, reality soon outstrips our attempts at satire. A correspondent reported to me the following real-life incident involving an American friend, who was told that her brother had died in an explosion.

She rushed to the hospital and was taken to the morgue to identify the body. It was indeed her brother. She bent to kiss him on the forehead and felt that he was still slightly warm, although the body had been refrigerated. She felt his hand and thought she detected an infrequent pulse. Amazed and alarmed, she called for a nurse. This nurse felt the body briefly and agreed that it was indeed still warm, but commented, ‘That’s odd, but you needn’t worry about it, dear, because it says here on this chart quite clearly that he’s dead’. This pronouncement delivered, the nurse calmly walked away. The

friend ran into the corridor, and frantically grabbed a passing doctor, who assessed the situation, gave her brother intracardiac adrenalin, and successfully resuscitated him. He still lives.

What, you may ask, has that got to do with hemispheres? Let me explain.

As readers of *The Master and his Emissary* will know, in 1996, in an extraordinary and elegant piece of research, the prominent Anglo-American neurologist Marcel Kinsbourne and a Russian colleague Vadim Deglin conspired to investigate how the two hemispheres of the brain reach conclusions about what is true.²⁵ To say, as they modestly do, that aspects of the results are ‘revealing’ and even ‘remarkable’ is, I believe, an understatement. (I referred obliquely to this experiment in Part I.)

By a procedure that temporarily suppresses one hemisphere at a time, they were able to ask the two halves of one and the same individual’s brain the same questions and compare the answers they received.²⁶ This gave them a window, just for about 15 minutes, into each hemisphere’s world. And what they asked was simply whether the conclusion of each of five syllogisms was true. How controversial could that be?

A syllogism is a logical structure whereby two propositions (or ‘premisses’) taken together lead inevitably to a conclusion. The classic example is:

1. All men are mortal;
2. Socrates is a man;
- therefore:
3. Socrates is mortal.

We can imagine this formulated as a question: ‘Given 1 and 2, is Socrates mortal or not?’ The answer is obviously ‘Yes, he is.’ This is the way Deglin and Kinsbourne configured their investigation. In the experimental examples, however, there was a cunning twist. In each syllogism, one of the premisses was false. So was the conclusion true, or not?

Here’s an example:

1. All monkeys climb trees [so far so good];

2. The porcupine is a monkey [not so good];
3. The porcupine climbs trees.

Is this true? As you can see, the issue is not quite straightforward. So how would you answer?

(Between you and me, there are, annoyingly, porcupines that climb trees. So before someone points it out, I should say that this fact was clearly not known to the investigators or their Russian subjects, and for the present purposes we can put that out of our minds.)

The point at stake is one that is familiar in Western thinking since Aristotle: between a *valid* argument and a *sound* one. An argument is said to be valid if its logical structure, as here, is correct. It is only said to be sound if *both* the structure *and* the premisses are correct, which here one of them clearly is not.

The experiment was carried out using the same five test syllogisms on 10 different subjects, each three times over, first in the normal state and then with just one hemisphere functioning at a time, yielding 150 results overall. And as we can glean from those results, it is clear how most of us normally answer. We normally reply that the conclusion is false, because, fairly obviously, the porcupine is not a monkey.

But what happens when we take one hemisphere on its own?

When the right hemisphere alone is asked, it replies, with some indignation, that the porcupine is ‘not a monkey, it’s prickly like a hedgehog, it is wrong here!’ However, when the isolated left hemisphere alone is asked, ‘the same subjects changed their answers dramatically’.

As the authors point out, the subject’s ‘*attitude to false premises* changed radically’. When the left hemisphere of the very same individual, the one that has previously given the indignant response, is asked if the conclusion is true, it replies that, yes, ‘the porcupine climbs trees, *since it is a monkey*’. When asked by the examiner ‘but is the porcupine a monkey?’, the subject replies that she knows it is not. Nonetheless when asked again, she repeats that ‘since the porcupine is a monkey, then it climbs trees’. Again challenged by the examiner – ‘but you do know that a porcupine is not a monkey?’ – she insists on her answer. Why? Because ‘it’s written so on the card’.

Here is another example, from a different subject, using a different syllogism:

1. Winter is cold in tropical countries [untrue];
 2. Ecuador is a tropical country [true];
- question:*
3. Is it cold in winter in Ecuador, or not?

Right hemisphere response:

Subject: [shrugs her shoulders] Winter is not cold in tropical countries! It's a lie!

Left hemisphere response *of the very same individual:*

Subject: [reads quickly and answers immediately] It's cold in winter in Ecuador, because Ecuador is a tropical country.

Examiner: *Oh, is winter really cold in tropical countries?*

Subject: I think so. Winter is cold there and summer is warm.

Examiner: *Are you sure of this?*

Subject: No, I am not.

Examiner: *Ecuador is a tropical country, then, can it be cold there?*

Subject: No, it can't be since it is a tropical country ...
(the same syllogism is presented again):

Subject: It is cold in winter in Ecuador because Ecuador is a tropical country.

Examiner: *But you do know that it is not so.*

Subject: But it is written here.

The results were consistent across the 10 subjects. In fact one subject answered *all* the questions empirically – by reference to real-world knowledge – when in the normal state, as well as when using only her right hemisphere; and answered them *all* formally – according to the internal logic of the system – when using only her left hemisphere.

It is relevant that ‘the right hemisphere ... relates the sign to its referent. For the left hemisphere the relation of the sign to its referent is of less importance than for the right hemisphere; the left hemisphere deals with *the interrelation of signs*.’²⁷ Thus helping us to identify in the thrust of some postmodern philosophy the triumph of the left hemisphere.

As far as the left hemisphere is concerned, truth is fidelity to a closed system which defines its own reality. Internal, theoretical, consistency is more important than truth to experience. The right hemisphere, meanwhile, thinks that it might be worth checking by looking out of the window, where, whatever it may say on the piece of paper, a porcupine is not, actually, a monkey, nor are tropical winters cold.

Note the left hemisphere’s take is not to be confused with ‘coherence’ theory, which implies that a statement is judged true if it coheres with all one’s other beliefs. By that standard the assertion that a porcupine is a monkey cannot be held to be true, nor can anything that flows from it. Nor should the right hemisphere’s take be confused with ‘correspondence’ theory, whereby what the mind conceives is an accurate representation of something outside the mind. It is just much more loyal to truth as something that arises through experience than something asserted by an abstract system, the rules of a (finite) game.

CONCLUSION

In this chapter we have considered not what and how each hemisphere might contribute to the main paths humans have followed in their quest for truth – that will come in subsequent chapters; but how each would see the nature of truth itself. I suggest that the left hemisphere would see it as a *thing*, certain, fixed, and independent of our interaction with it, standing outside time and concerned with the consistency of a representation. By contrast, I suggest that the right hemisphere would see it as a *process*, always contextual, forever coming into being through our present interaction with the world in time, but nonetheless real for that – indeed, real *because* of that, because constantly tested against experience. I believe we often behave as though either truth is as the left hemisphere sees it, or else it does not exist. But, crucially, these are not the only options.

Further, let me emphasise that *both* the views currently on offer in so much public debate today – naïve positivism and naïve deconstructionism – are typical left hemisphere fictions. It is not that the first is left hemisphere-congruent, and the second right hemisphere-congruent. Each is an ill-concealed power grab, completely lacking in subtlety, and devoid of any sense of our true connection with the world. The ‘betweenness’ in which fidelity can operate has been lost: that is only understood properly by the right hemisphere. That there is ultimately no certainty (except in mathematics) is emphatically not an invitation to promulgate your latest theory based on some political ideology: the dangers in this are every bit as great as in adhering too closely to the reductionist materialist picture – possibly greater, since they derive from a position for which every point of view, every statement, is as valid as any other. That brings an end to truth, and hence to civilised discourse: indeed, an end to civilisation. Unfortunately, naïve positivism may ultimately lead there, too.

In Part I of this book I looked at the evidence that each hemisphere is or is not a reliable witness to the truth about reality. I use the term in the Pragmatist sense that, in Susan Haack’s formulation, ‘if what one believes

is true one is, so to speak, guaranteed against recalcitrance on the part of experience'. I was concerned there with the *means* of this kind of truth, the portals through which it can be discerned.

In Part II I will argue that each hemisphere is indispensable to a proper understanding, and that each makes a contribution, though in the modern West we are often misled by the left hemisphere's inveterate tendency to neglect the right hemisphere's contribution and 'go it alone'. I made the analogy between a pilot avoiding a plane crash and a philosopher coming out of his encounter with reality unbruised. In the modern Western world, we are constantly crashing, and puzzled as to why; constantly faced with paradoxical outcomes to our actions, what particle physicist and quantum theorist David Bohm called 'sustained incoherence'. We often find that we strive for something and achieve its precise opposite. Why is that? I suggest it is because our currently dominant model of reality is mistaken.

As a result, we badly need to rethink.

SCIENCE & TRUTH

It happened to him as it always happens to those who turn to science ... simply to get an answer to an everyday question of life. Science answered thousands of other very subtle and ingenious questions ... but not the one he was trying to solve.

—*Count Leo Tolstoy*¹

SCIENCE'S CLAIMS ON TRUTH

The antagonism between science and metaphysics has, like all family quarrels, been disastrous.

—*Alfred North Whitehead*¹

Science and metaphysics are inextricably united, and stand or fall together.

—*RG Collingwood*²

WHERE WOULD MOST OF US NOW, IN THE WEST, LOOK FOR TRUTH? SURELY the answer has to be science – science which has taken over from religion as the lodestar of our age. In an era of materialism, where the speed of societal change and the fusion of peoples have made traditional cultural values problematic, science alone holds out the promise of stable knowledge on which we can rely to build our picture of the world. And, within certain important limits, it is a promise that is certainly not in vain. People who ignore science are either afraid of it, because they don't understand it, or find its truths inconvenient. Science is a guiding light: if we put it out, we are in the dark. And precisely because it is so precious, we should be careful to guard it from ever-present dangers – exaggerated claims, models that distort, and institutional pressures, which effectively destroy its power and lead us into error.

In this chapter I want to look at the contribution science can make to our understanding of the world. Note, an *understanding of*, not just *knowledge about*: ‘knowledge, as an instrument of human progress’, writes physicist Claudio Ronchi, ‘can become, like the Gorgon, a goddess that transmutes anyone who gazes upon her into stone.’³ I will suggest that its contribution is of great value, but that there are intrinsic limits to what it can be expected to tell us, and that these limits all too often go unrecognised.

As someone whose practice and research depends on science, I have only respect for its proper aims and ambitions. Science is an essential part of our enquiring nature, and brings the potential for much that has transformed our lives for the better. No scientist is more frustrated than I am by those who dogmatically disregard its findings, especially where, in my field of medicine, those findings have power to save lives; and no-one could be more conscious of, or grateful for, the interminable scientific labours of others, from which I have hugely benefitted, in my work, in my practice, and in my life.

Yet science cannot possibly fulfil the burdensome role of sole purveyor of truth. This is not a failing in science. Good science is aware of its limitations. Scientism, the belief that science will one day answer all our questions, is not.

Some philosophically naïve individuals become very exercised if they sense that the status of science as sole purveyor of truth is challenged, as some of the less edifying exchanges on the internet testify. So let me make very clear at the outset that my purpose in what follows is to establish ourselves on a firmer footing in relation to science, by drawing attention to the quicksand in which we might otherwise go down. The greatest scientists, as we shall in due course see, have been well aware of these problems, even if they couldn’t have couched their warnings in terms of the hemisphere hypothesis. But very often the practice of science is not so self-aware; and then its propaganda about itself – the claims it wishes to make about both the truth of its discoveries and the exclusive validity of its approach to truth (‘thou shalt have no other gods before me’) – leads not so much to science, as to scientism.

It is obvious that science is heavily dependent on the exercise of what the left hemisphere offers. Science’s successes, in explaining how the world works and in helping us to control and manipulate that world to the extraordinary degree to which we now do, are unquestionable, and are

dependent on precisely those specific capacities which the left hemisphere contributes, capacities of analysis and for identifying mechanisms. There is no gainsaying that and I have no wish at all to gainsay it.

But we have seen in Part I what could be called the double problem of the left hemisphere: its inferiority, compared with the right hemisphere, in its receptiveness to and understanding of whatever it encounters; and, more dangerously, its tendency to mistake its re-presentations of reality (its simplified versions of what it encounters and its explanations of how those simplified versions work) for reality itself. It all too often then attempts to deny the right hemisphere any further role in the proceedings and seeks to persuade us that its necessarily partial re-presentations provide us with the wider understanding to which we aspire and to which we like to attach the word 'truth'. This is the hubris of the left hemisphere, beset with unknown unknowns, overconfident in its own prowess, while taking the upper hand. We have watched this in action in Part I.

In the next chapter I will explain why I am concerned by the harm done to science by the myopic effect of the models it sometimes espouses, by which we are needlessly depriving ourselves of scientific insights. And, finally, in the subsequent chapter, I will demonstrate why the scepticism that science officially espouses needs to be brought to bear on the 'science industry' itself, which is no more infallible instrument of true science than any church establishment is of true spiritual wisdom. But first, in this chapter, I want to look more fundamentally, in the context of the hemisphere hypothesis, at the boundaries of science's ambitions legitimately to tell us what is truthful.

UNDERSTANDING, EXPLANATION, METAPHOR AND MODELS

Let me begin with some very simple questions. The simplest questions are the trickiest. ‘How?’, ‘what?’, and ‘why?’ are particularly slippery. If I ask ‘how did she respond?’, you could answer ‘using her vocal apparatus’; or, understanding ‘how’ differently, you might say ‘with some scepticism, but not without her usual willingness to help’. Similarly if I ask ‘what causes an apple to drop from a tree?’ you readily reply ‘gravity’; but if I ask ‘what, actually, *is* gravity?’, you (ought to) pause, and will soon find yourself tied up in an infinite maze of self-referring propositions. Science can deal in each case with the first type of question, in which an explicit, mechanistic explanation is enquired about, and the accompanying framework that makes it comprehensible is taken for granted; but not in the second, in which that framework is transcended. And every toddler demonstrates that the question ‘why?’ can be carried on till all frameworks and mechanisms are transcended, and the reply has to be either ‘That’s just the way things are’, or ‘now you go to bed’.

Grasping what ‘with some scepticism, but not without her usual willingness to help’ means cannot be achieved through a framework of mechanical explanation; it requires something much more diffuse and implicit – understanding, the product of human experience. The first, explanation, is the left hemisphere’s mode; the second, understanding, the right hemisphere’s, albeit often enriched by the contribution of the left.

Explanation, science’s forte, is a subset – an explicit, rigorous, disciplined subset, but still a subset – of understanding. All understanding depends on metaphor. What we mean when we say we understand something is that we see it is like something else of which we are already prepared to say ‘I understand that’. That, in turn, we will have understood because we have likened it to something else we had previously understood, and so on. It’s metaphors all the way down.

In science this inescapable role of metaphor is manifest in the model the science uses in order to seek an explanation of the phenomenon it is investigating. Models are simply extended metaphors. The choice of model is crucial here because the problem for seekers after truth is that that choice

governs what we find. We find more or less according to what we put there. Since a model always highlights those aspects of what it is modelling that fit the model, any model soon begins to seem like an uncannily good fit, which means we espouse it with still greater confidence. And, as they say, to a man with a hammer, everything begins to look like a nail.

Even the sense-data that go into selecting the model are not innocent. Perceptions are laden with theory. We never just see something without seeing it *as* a something. We may think that our theories are shaped by observations, but it is as true that our observations are shaped by theories. This means we can be blind to some very obvious things in our immediate environment. We don't look where we don't expect to see, so that our expectations come to govern what we *can* see. This is why the model is crucial. In the past such a model was often something in the natural world – a tree, a river, a family. Nowadays, unless otherwise specified, it is the machine.

That a machine should be attractive as a model to science's helpmate, the left hemisphere, hardly needs – well, explaining. Machines are put together from parts and the left hemisphere's mode of operation is to break phenomena down into parts and then see how they can be put together again. Furthermore, putting parts together to make machines aids the left hemisphere's purpose: manipulation and control. So it is not surprising that for at least the last 250 years, the era in which science has enjoyed its most spectacular successes in explaining how the world works, and enabling us to use those explanations to manipulate and control it according to our purposes, the machine model should have been the default model in science. In the popular mind it remains science's defining paradigm.

Yet the machine model remains only a model, a form of metaphor. However productive it may have been in explaining and manipulating the world, it is still no more than a metaphor. As we shall see, even at the relatively lowly level of explanation it has exhausted its potential, something that was obvious in physics some time ago, and is becoming increasingly obvious in the life sciences. In other words, it doesn't fit with a multitude of important findings that can't be ignored.

The left hemisphere, however, is apt to forget, in the glow of its explanatory and manipulative successes, that in relation to truth, those successes are built on the absolutely necessary but inevitably shaky foundations of metaphor. Scientists often try to brush aside what they seem

to regard as this embarrassing fact. Models, which are extended metaphors, partial though they inevitably are, cannot be dispensed with, since understanding always involves seeing similarities to and difference from something else we think we understand. For example, Philip Ball (whose writings I generally admire), writing in *Nature*, opines that metaphors ‘at the very least, should be admitted into science only after strict examination.’⁴ Leaving aside the fact that the criteria by which any metaphor could be examined are themselves already derived from the application of a model, so that what one would be examining would be – not the intrinsic merit of the metaphor, but – whether it accorded with one’s already unexamined and taken-for-granted metaphor; and leaving aside the question how metaphors could be ‘admitted into’ science in a way that makes any such entry examination feasible; and leaving aside the issue of who we are going to entrust with the task of appraising them, since opinions about the applicability of individual metaphors will always differ, the whole idea is incoherent. Does he think that somehow we could get by for an instant without metaphors? Like many others he quotes the ‘warning’ attributed to cyberneticists Arturo Rosenblueth and Norbert Wiener: ‘The price of metaphor is eternal vigilance’, as if shaking his head over those who haven’t the strength of mind to divest themselves of the metaphor habit, and muttering ‘this will end in tears, you know’.

As a matter of fact, I cannot find that Rosenblueth & Wiener ever said this,⁵ but the sentiments are surely correct, even if not as Ball seems to have read them. That’s because the price of the pursuit of knowledge by any means whatever is eternal vigilance. However, the price of trying to think without metaphor would not only be eternal vigilance, but eternal vacuity. It’s as if someone were to say, the price of having tyres on your car is eternal vigilance. True, but there are risks in life that can’t be avoided if we are to get anywhere at all.⁶ The price of *doing science* is eternal vigilance, and not just because it can never avoid using metaphor.

What Rosenblueth & Wiener definitely do say is that since ‘the best material model for a cat is another, or preferably the same cat ... partial models, imperfect as they may be, are the only means developed by science for understanding the universe’. We can’t do without them, but we need to be sure the ones we have – this is the real point – are as little misleading as possible.⁷ And it’s the type of scientist who thinks he is not *inevitably* using metaphors and models that is most worrying, because unaware of the

pitfalls. We need to be vigilant in our use of metaphors, not because there is something dodgy about metaphor in general, but because there is something dodgy about many of the ones currently espoused by mainstream science. There I am in wholehearted agreement. We don't see what our metaphors blind us towards. This is the subject of Chapter 12.

All models are in this way a partial fit, giving a selective view of the matter. As the mathematician and philosopher Alfred North Whitehead puts it in *The Function of Reason*:

The man with a method good for purposes of his dominant interests, is a pathological case in respect to his wider judgment on the coordination of this method with a more complete experience. Priests and scientists, statesmen and men of business, philosophers and mathematicians, are all alike in this respect. We all start by being empiricists. But our empiricism is confined within our immediate interests. The more clearly we grasp the intellectual analysis of a way [of?] regulating procedure for the sake of those interests, the more decidedly we reject the inclusion of evidence which refuses to be immediately harmonized with the method before us. *Some of the major disasters of mankind have been produced by the narrowness of men with a good methodology.*⁸

Whitehead makes a distinction between what he calls 'the authority of science in the determination of its methodology' and its lack of authority in determining what counts as an explanation, let alone an understanding. And he points to the 'natural reaction of men with a useful methodology' against any evidence tending to limit the scope of that methodology:

Science has always suffered from the vice of overstatement. In this way conclusions true within strict limitations have been generalized dogmatically into a fallacious universality.⁹

Dogmatism inevitably obscures the nature of truth. He continues:

Obscurantism is the refusal to speculate freely on the limitations of traditional methods. It is more than that: it is the negation of the

importance of such speculation ... A few generations ago the clergy, or to speak more accurately, large sections of the clergy were the standing examples of obscurantism. Today their place has been taken by scientists ... The obscurantists of any generation are in the main constituted by the greater part of the practitioners of the dominant methodology. Today scientific methods are dominant, and scientists are the obscurantists.

The point is that we cannot discover whatever aspect of truth is revealed by a certain approach unless we commit ourselves to it sufficiently to find out; but by the very act of doing so, other aspects of truth become concealed, aspects which, when pointed out by others, will tend to be unrecognised, or ultimately dismissed.

‘In our time’, wrote the distinguished biochemist Erwin Chargaff, whose discoveries paved the way for Crick and Watson, and whose intellectual autobiography *Heraclitean Fire* should be read by every scientist,

so-called laws of nature are being fabricated on the assembly line. But how often is the regularity of these ‘laws of nature’ only the reflection of the regularity of the method employed in their formulation! ... Science is still faced with the age-old predicament, the lack of ultimate verification. ¹⁰

And he continues, in wise words,

In general, it is hoped that our road will lead to understanding; mostly it leads only to explanations. The difference between these two terms is also being forgotten ... These are two very different things, for we understand very little about nature. Even the most exact of our exact sciences float above axiomatic abysses that cannot be explored. It is true, when one’s reason runs a fever, one believes, as in a dream, that this understanding can be grasped; but when one wakes up and the fever is gone, all one is left with are litanies of shallowness. ¹¹

OBJECTIVITY

It would, of course, be absurd to dismiss the vast library of scientific knowledge as ‘litanies of shallowness’, and that is not what Chargaff intends. Rather, he is insisting on the vital difference between explanation and understanding. And, in speaking of ‘axiomatic abysses’ he is referring to aspects of scientific knowledge which we tend to take for granted but which need examining. None is in greater need of such examination than the notion of objectivity, a concept which we probably cannot do without, but which it is all too easy to misinterpret.

The popular, received view of objectivity goes something like this. We are here and the world is there. We are ‘subject’ and it is ‘object’. We want to have knowledge of how, in itself, the world really is. Science provides us with that objective knowledge by taking ‘us’ out of the picture, so removing subjective distortion from its objective presentation of how, in itself, the world actually is. This account of objectivity goes back at least as far as Descartes and underpins the popular view of why, since Descartes’ time, science has enjoyed such extraordinary prestige.

We have already seen, however, that this aspiration to take ‘us’ out of the picture is compromised by the fact that science can’t get going without metaphor and metaphor is something from which ‘we’ cannot possibly be divorced. But that is only a specific case of a more general point about how we cannot remove ourselves from the picture in the way this crude and misleading interpretation of objectivity requires. To put it bluntly, science, at least since the time of Descartes, has attempted to excise the most important part of any understanding, namely that, obviously enough, it is grounded in, takes place in, and is meaningless without, the human mind, and its capacity to understand.

To the extent that we have knowledge or experience of the world on which to base an understanding, we cannot know what it is like when we don’t know it. The existence of a distinct practice known as physics (which was not the case until the last few hundred years) alters what we see and take notice of, what we see but ignore, and what we may entirely fail to see; and it alters how we interpret our results, and their ultimate meaning, which is inevitably determined both by the individual doing the physics, and, since

no individual exists separate from a culture, by the often hidden assumptions of that culture. Human knowledge can only be more or less true – though, to be *absolutely* clear, this does nothing whatever to diminish the importance of truth. What we know cannot escape the fact that it is human knowledge; and we could fully know the qualities and limitations of *that* only by getting outside it, and having something else to compare it with – which is a logical impossibility.¹² As Max Planck, one of the founding fathers of quantum mechanics, pointed out, ‘science cannot solve the ultimate mystery of nature. And that is because, in the last analysis, we ourselves are part of nature and therefore part of the mystery that we are trying to solve.’¹³

Objectivity is always someone’s position, situated somewhere, and making some assumptions. There is no such thing as the ‘view from nowhere’. But there is such a thing as a view derived from considering as many positions as possible. We must not forget that scientists – like philosophers – are human beings, with personalities, temperaments, and experiences of life, all of which they do not hang up in the locker room when they put on their white coats. Although objectivity, in the sense of a fair consideration of all possibilities, is an honourable and necessary aim, objectivity in the sense of adopting a viewpoint that makes no presuppositions is intrinsically impossible to achieve. ‘We all, scientists and non-scientists, live on some inclined plane of credulity’, wrote William James. ‘The plane tips one way in one man, another way in another; and may he whose plane tips in no way be the first to cast a stone’.¹⁴

The Russian film-maker Andrei Tarkovsky pointed out that ‘objectivity can only be the author’s, and therefore subjective, even if he is editing a newsreel’. Any statement about anything is always both an inclusion and an exclusion, its meaning derived both from what is said and what is not: choices are always involved. This is not a point about documentary film-making, but about life. Ideas, including scientific ideas, do not live suspended in a vacuum, but have relationships across time, and at a point in time, with others, forming out of observed regularities the ‘models’, ‘laws’ and ‘principles’ which are our own creations, shaped as much by what they do *not* include as by what they do.

Adding to their contingency is a simple and very obvious point, the limitation imposed by our sense organs – and our brains. We can’t detect what our sense organs do not permit us to detect: there may be senses that

we could have had, but don't, which would have revealed other aspects of the world to our understanding and which we are incapable of imagining – could we have imagined what it is like to hear, if we had only sight, smell and touch to go on? When aboriginal people say that they can hear, or see, or sense things that we cannot, how do we know they are wrong? And the senses we do have are limited in extent: we can't hear what bats and bears take for granted in their world. It would be irrational to suppose we are directly aware of more than a little of what exists. Why assume that our cognition is capable of more than a few limited forays into the vastness of reality? Evolution is a process. We know more than mice (though there must also be things they know that we don't). A more highly evolved creature may one day regard our understanding of the world much as we now view that of the mouse.

'The wise scientist', wrote Chargaff, 'will be aware of the eternal predicament that between him and the world there always is the barrier of the human brain.'¹⁵ That is one way of looking at it. Another would be that, like every shared boundary, it can act to separate or unite, act as a barrier *or* as point of contact: the ear drum is a boundary, but one essential to hearing. It's just that we need to be aware, as Chargaff suggests, that we can only know the world as our brains construe it; and in every brain there are at least two internally coherent versions of the world that conflict. Science must take this into account when it talks of objectivity.

Observations are not as simple as they are conceived to be, even if there is apparently complete agreement between a number of them. 'Whether you can observe a thing or not depends on the theory which you use', as Einstein pointed out.¹⁶ According to philosopher of science Norwood Hanson, referring to a famous optical illusion in which figure and ground are reversible, two 'drawings might be indistinguishable. I see a goblet, however, and you see two men staring at one another. Do we see the same thing? Of course we do. But then again we do not.' Note, by the way, that though the image can be seen as two quite different things, it can't be seen as just any old thing. It can't be seen as a rabbit, not even a duck-rabbit. Our alternatives are not single truth or chaos. And Hanson continues that to conclude that scientists

make the same observations but use them differently is too easy ...
Were there no sense in which they were different observations they

could not be used differently ... There is a sense, then, in which seeing is a ‘theory-laden’ undertaking.¹⁷

He uses the example of Tycho Brahe and Johannes Kepler registering the same sense-data on seeing the sun rise, but seeing something quite different – since Brahe, unlike Kepler, believed the position of the earth was fixed. Advocates of different scientific theories clash because they see the same sense-data differently and use the same words to refer to what are in fact distinct conceptions: competing theories lead to differing observations as much as differing observations lead to competing theories.

If this is fatal to objectivity as it is commonly, and naïvely, understood, it is absolutely not fatal to the best motives that lie behind the wish to claim objective status. As scientists or citizens, we rightly fear the loss of a hierarchy of value, the loss of grounds for believing that some judgments are to be preferred to others, that some statements are inevitably truer than others. Indeed, the flawed fact-value distinction is itself an *appeal* to value – the value of ‘facts’ – and is in turn *based* on value – inevitably and rightly – not on fact. And it stems from an honourable, noble urge: an allegiance to truth. It’s just that it ends up in the mistaken assumption of a subject-object divide.

According to Polányi scholar CP Goodman,

[Michael Polányi] notes that all methods, even the most formalised, rely upon our judgements. It is not possible to absent ourselves, and nor should we try. If all knowing involves the participation of a knower, then it follows that all knowing is a form of valuation. We make judgements about what we ought to believe. Our beliefs may be mistaken, but they are not arbitrary. They are guided by our tacit awareness. In his analysis of the structure of tacit knowing – his key contribution to philosophy – Polányi seeks to reconcile fact and value (which in the modern period have been broken apart).¹⁸

Just because we can’t measure values, they are neither less important, nor less rightly operative, in science: the confusion comes from science’s reluctance to accept as real what cannot be pinned down and measured. It therefore unwittingly drives itself into a cul-de-sac: the false divorce of fact

from value. Note that the *distinction* is valid: it is the *divorce* that, as so often, causes the problem. Science frequently passes over entities, however important they may be, that cannot be measured. Attempts to evaluate systems often end up measuring what can easily be measured, rather than what actually matters, but can't be measured.

Science places a very high value, too, on precision and consistency. But what about those things that are either intrinsically imprecise, can't be generalised, change their nature when made explicit, alter with the very fact of observation, or tend to fluctuate widely in their manifestations? They are still real, and some of them are very important. I don't say there are no scientific ways of dealing with them, just that in practice it is much harder – and it often doesn't happen. As biochemist Addy Pross remarks:

Some characteristics of undeniable scientific interest are inherently difficult to quantify, or are even unquantifiable. Attempts to quantify the unquantifiable will be unrewarding and may only lead to confusion.¹⁹

And what about those cases where apparent opposites come together, where light is both wave and particle, or where, as in the human sciences, to be wholly rationalistic may well be irrational?

What we should conclude is not that the unimpeachable drive behind the crudely interpreted concept of objectivity is mistaken, but that we should be more nuanced in our interpretation. It is an enterprise, a continuing process, not a 'thing' that could ever be finally achieved. It involves a habit of mind and spirit, not the following of external procedures or rules. Put another way, the 'objectivity' lies not in propositions, but in a disciplined disposition; in a modest recognition that our existing answers are inadequate, and in a constant awareness of limitations in handling the possible alternative, always provisional, answers. The foundations of physical reality can never be known with any certainty: as Gleiser puts it, 'in the quantum realm the very question of trying to know more, of trying to go beyond the limits imposed by uncertainty, doesn't make sense ... Final theories are incompatible with the scientific method. Given that we can only accrue scientific knowledge from measurements of natural processes,

it is by definition impossible to be certain that we know all the forces of Nature or the fundamental particles that exist.’²⁰

This has nothing to do with the deeply pernicious – not to say incoherent – view that anything goes. Pernicious, because it effortlessly exalts any cracked ideology to the same level as the distilled wisdom of a civilisation, and thereby debases the distilled wisdom of a civilisation to the level of any cracked ideology. Incoherent, because, if anything goes, nothing goes: we no longer have any purchase on reality. My position is that almost nothing goes: the whole purpose of education, self-discipline and scholarship being the honest, open and humble attempt to find whatever lies in that space closest to the truth, in the knowledge that success is always a matter of degree. But that degree is of the utmost significance.

From experience we know that our own views can be more or less faithful accounts of what, from everything we know, we can reasonably claim to be the case. The ‘more or less’ depends on a range of circumstances, all tending to converge on the degree to which we are inclined to consider *different* points of view. Generally we get better at this with maturity, though both temperament and intelligence are bound to play a part in inter-individual differences. This process could be thought of as the habit of tempering truths with their true opposites. Truth is a matter not merely of quantity, but of quality; not just of degree, but of the manner of its holding.

As John Stuart Mill so wisely said (speaking about social science, but it applies more widely):

All students of man and society who possess that first requisite for so difficult a study, a due sense of its difficulties, are aware that the *besetting danger is not so much of embracing falsehood for truth, as of mistaking part of the truth for the whole*. It might be plausibly maintained that in almost every one of the leading controversies, past or present, in social philosophy, both sides were in the right in what they affirmed, though wrong in what they denied; and that if either could have been made to take the other’s views in addition to its own, little more would have been needed to make its doctrine correct.²¹

Mill's point about 'mistaking part of the truth for the whole' is echoed by Whitehead: 'There are no whole truths; all truths are half-truths. It is trying to treat them as whole truths that plays the devil.'²² And, with particular relevance to science:

In scientific investigations the question, True or False?, is usually irrelevant. The important question is, In what circumstances is this formula true, and in what circumstances is it false?²³

The neglect of context or circumstance sacrifices subtlety to 'all or nothing' answers. Science tends to take things out of context – in fact, many would say that this is exactly what is special about a genuinely scientific explanation. I have written about the problem of decontextualisation elsewhere, and the significance of this fallacy in every aspect of life.²⁴ John Dewey thought it the most serious mistake philosophy can make, and it inevitably results in a distorted account of whatever it aims to illuminate.²⁵

Science is the stronger for being freed from the superstitious beliefs that are foisted on her by her false friends, those who are in love with certainty and need to know they are right (there are many of these in religion, and in politics, too, so science is not alone). There is among many of the public, as Nassim Nicholas Taleb points out, 'a religious belief in the unconditional power of organised science, one that has replaced unconditional religious belief in organised religion ... We have managed to transfer religious belief into gullibility for whatever can masquerade as science.'²⁶ No good is done to science by making the inflated claims that, unfortunately, some naïve scientists do make on her behalf – thinking that they thereby do her a favour. Obvious discrepancies between the excessive claims of any culture and human experience lead eventually to a countermovement that ends in disaster: the baby gets thrown out with the bathwater.

The danger of the claim that science provides full and 'objective' truth, in the crude sense of that word, is that as soon as it becomes apparent, as it readily does, that this way of understanding objectivity is not watertight, the whole ship is in danger of sinking: its apparent robustness – a hard and fast, all or nothing, supposedly cast-iron concept – renders it fragile. A Titanic claim invites disaster when the ship collides with the inevitable iceberg of philosophical reflection. For then, the only options become total

impregnability or a shipwreck: science is either high and mighty or 'just a matter of opinion', like any other. Neither of these positions is supportable: each is dangerous. And so it is that another untruth triumphs in their place: the malign idea that science cannot be distinguished from claptrap.

HIDDEN ASSUMPTIONS

‘Science doesn’t think’, as Heidegger put it. ‘*Science* doesn’t venture into the *realm of philosophy*. It is a realm, however, on which, without her knowing it, she is *dependent*.’ ²⁷

Earlier I quoted Erwin Chargaff’s remark that even the most exact sciences float above ‘axiomatic abysses’: unexamined assumptions. It is a tenet of science that its basic intellectual aim is to improve knowledge about the world, nothing being permanently presupposed about the world independently of evidence. But ‘to say, with the radical empiricist, that only factual statements have validity is to be not only dogmatic but self-contradictory, since the statement itself is not factual.’ ²⁸ Its ‘truth’ is an assumption based on intuition, not on any kind of fact, logic or science in itself. That is fine, but it needs to be acknowledged. So does the assumption that contraries are incompatible. After all, one of the greatest scientists of all time, Niels Bohr, adopted the opposite assertion – *contraria sunt complementa* – as his motto.

The philosopher of science Nicholas Maxwell has demonstrated at some length that the claim that science presupposes nothing about the world independently of evidence is untenable. ²⁹ For a start, it is not only presupposed by science that the universe is fully comprehensible (which means, inevitably, comprehensible by a human being), but presupposed that it is fully comprehensible *physically*. Thus matter, according to convention, can be assumed, but consciousness cannot – indeed, as is well known, there are philosophers who deny the very existence of consciousness.

‘To many working scientists’, writes philosopher Bryan Magee,

science seems very obviously to suggest an ultimate explanation, namely a materialist one; but a materialist view of total reality is a metaphysics, not a scientific theory. There is no possibility whatever of scientifically proving, or disproving, it. The fact that it is held by many scientists no more makes it a scientific theory than it can be said to be an economic theory because it is held (no doubt) by many economists. ³⁰

An element of faith is necessarily involved in the scientific process. That is in no way to the discredit of science, since all paths to knowledge whatever have to involve assumptions built into the model, as well as certain axioms, 'truths' that cannot be proven, but are taken for granted. Science requires a degree of commitment to an idea for a while until one finds out whether or not it works: without engagement many truths will escape us, which is why, inside or outside science, it is not an option to sit on the side-lines of life, waiting for 'objective' evidence to accumulate before making a commitment. Speaking of the elementary laws from which the rest of physics must be deduced, Einstein had this to say: 'To these elementary laws there leads no logical path, but only intuition, supported by being sympathetically in touch with experience.'³¹ This is Pragmatism, pure and simple: and, as the reader will know, I agree that we cannot do better than Pragmatism in any approach to truth.

Furthermore, science depends on the idea of cause and effect mechanisms, a phenomenon that parallels the logic whereby the left hemisphere puts back together the bits and pieces. But the concept of a cause is not transparently obvious. As used by scientists, the term 'causation' admits of at least seven, possibly more, meanings.³² According to the anthropologist Pascal Boyer, in scientific thinking 'the only stable "principles" are vague, unconstraining generalisations that', he argues, 'do not rule out magical connections'.³³ I would not go so far myself, but the point that when we construct formal relations of a causative nature these may issue in different kinds of understanding that are not necessarily explicit is well taken.

It is also assumed that the same principles that govern the part of the cosmos that we observe obtain everywhere and for all time; to abandon that tenet would be to threaten the terms on which an understanding of the universe as a whole could be achieved. But in fact, as Max Planck observed, 'we have no right to assume that any physical laws exist, or if they have existed up to now, that they will continue to exist in a similar manner in the future.'³⁴ All we know is that there are local habits in the part of the universe we inhabit.³⁵ Newton may have said *hypotheses non fingo* ('I don't make up hypotheses'), but at the same time his so-called 'Universal Law' of gravity was just that: a brilliant hypothesis.³⁶ That it was a law, let alone a universal one, he did not know then, nor do we know now.

As Pross writes in his interesting book *What is Life?*

In contrast to terms such as ‘theories’ and ‘laws’ which radiate some sense of absolute truth, the term ‘pattern’ is more subtle, less committed, less definitive, more open to modification. Even Newton’s laws, those pertaining to gravity and motion, have had to undergo revision following Einstein’s revolutionary insights. If we keep in mind that every hypothesis, theory, or law is ultimately just a pattern, the day that theory or law is modified or revoked will be less surprising, less disconcerting.³⁷

A further questionable assumption is that there is nothing purposive about the cosmos: something which we cannot know, requires the making of further assumptions, and in the end fits the findings no better than – arguably not as well as – the assumption of purpose (a complex issue to which I will return in Chapter 27). This does not exhaust the assumptions science makes.

My point here is simply to show that there are many assumptions built into science, for good or ill. These may be reasonable assumptions, but they are undoubtedly metaphysical assumptions, not deductions from evidence. The first of these assumptions, that the world is humanly comprehensible, is necessary for the great project of science to get off the ground, so it is an entirely reasonable assumption. But it is still an assumption, for all that, one that is usually forgotten, and it has consequences. If you assume that the world must be comprehensible in purely physical terms, that there are no purposes in Nature or the cosmos, and that contraries exclude one another, what you end up seeing and calling ‘truth’ will be different from what you see if you make no such assumptions.

Since one cannot become aware of what it is one is not aware of, the fact that a system or model works for certain purposes indicates only *that* – that it works – and no more. As the physicist and mathematician John von Neumann put it:

The sciences do not try to explain, they hardly even try to interpret, they mainly make models ... The justification of such a

mathematical construct is solely and precisely that it is expected to work.³⁸

It shows us what that model can show, but cannot help us see what it obscures. Science's explanations both reveal and conceal. Reducing assumptions to a minimum, as science certainly aspires to do, is a good principle; but we shouldn't run away with the idea that that minimum is very small, let alone that science has managed to dispense with assumptions altogether. And if reducing assumptions to a minimum is the goal, why is the greater assumption, that the world is physically understandable, preferable to the lesser assumption, that it is simply understandable? The assumed primacy of matter is something to which I shall return in Chapters 24 and 25.

THE MYTH OF THE SCIENTIFIC METHOD

One of the consequences of the post-Cartesian notion of scientific objectivity, of a world ‘out there’ that we ‘in here’ can gain objective knowledge of, is that ‘we’ must keep out of the method of enquiry. This has generated the reductive myth of the scientific method, an account of science operating in a deeply impersonal manner such that the scientist’s imagination almost entirely disappears from view. According to the myth, scientific knowledge arises from the rigorous, logically sequential unfolding of whatever follows securely from predictable procedures by calculation according to fixed laws. But this myth utterly fails to do justice to what the work of science actually involves. The sheer, staggering work of imagination and inspiration that is science, its discoveries unpredictable and recalcitrant to compulsion by laws or procedures – real, living science – is swept away in this myth, this representation of science as something pedestrian, uninspired, essentially bureaucratic – and dead. It renders science something that a computer could do better than human beings. The distinction between these two accounts of science is the one Chargaff makes between rare, genuine scientists and drudges in the vast institutional machinery of science. Readers will spot, in the myth’s deathly representation of scientific life as merely following procedures, the signature of the left hemisphere, and its grandiose aspirations to certainty. ‘Science is no longer identified with certitude and probability with ignorance,’³⁹ wrote Ilya Prigogine. In fact, science is a matter of probability and certitude a matter of ignorance.

Oddly, despite so much evidence to the contrary, it still needs emphasising that in practice science progresses by many more fruitful routes than the fabled ‘scientific method’. After describing the textbook version, George Gaylord Simpson, one of the most influential contributors to the reigning ‘Modern Synthesis’ in genetics, observes:

It quite ignores the most difficult, most creative, and most important elements of scientific endeavour. How does one discern a problem, or decide what kinds of questions are to be asked? How does one determine what observations are relevant? And especially, what kind

of hypothetical solutions are acceptable and where do they come from? Perhaps the most cogent objection of all is that important basic research has seldom really followed the ‘method’ just as it is stated.⁴⁰

In other words, you can’t even start on the scientific method without making assumptions, using judgment and having insights, insights that are not part of the method, and do not follow any kind of formal principles – and the method is in any case unlikely to produce ‘important’ results.

The process of science has much less to do with logic than has classically been assumed.⁴¹ ‘Science-in-practice is often driven by hunches and vague impressions’, according to Yale psychologists, Leonid Rozenblit and Frank Keil, who have studied how much we know and how we come by such knowledge in various settings.⁴² For a start, science depends on good hypotheses. Not only is there nothing wrong with that, but it is essential to the nature of science that it imaginatively selects its assumptions, which it discards only when they don’t work. Newton need not have been so defensive about dealing in hypotheses.

Science could never get off the ground if untold numbers of fruitless hypotheses had to be taken equally seriously and subjected to the same procedure so that they could be systematically eliminated. It therefore requires the exercise of imagination from the outset, which alone can supply interesting and potentially fruitful hypotheses, and eliminate intuitively unfruitful ones. While respecting the data out of which they emerge, good hypotheses always ‘go beyond’ the immediate facts.

As the biologist Peter Medawar wrote,

Scientists should not be ashamed to admit, as many of them apparently are ashamed to admit, that hypotheses appear in their minds along uncharted by-ways of thought; that they are imaginative and inspirational in character; that they are indeed adventures of the mind.⁴³

Anna Sfard, a professor of mathematics, has studied the ways in which scientists and mathematicians reach their conclusions. From interviewing them at length, she concluded that

it was quite clear that, for them, one of the best indications of understanding is the ability to sense that something is true in an immediate manner, without having recourse to a formal proof ... 'Having a result' without knowing how it was obtained is perhaps the most striking phenomenon in the work of a mathematician.⁴⁴

This could be seen as a direct account from experience of how the right hemisphere first intuits something as a *Gestalt* before the left hemisphere sets about systematising it. 'I hope no one still thinks that theories are deduced by strict logical conclusions from lab records', wrote Wolfgang Pauli, a pioneer of quantum physics, in 1957, 'a view which was still all the rage in my student days. Theories arise from *seeing* something inspired by empirical data'.⁴⁵ Scientists who think science consists of unprejudiced data-gathering without speculation aspire, in Medawar's phrase, merely to 'browse over the field of nature like cows at pasture'.⁴⁶

That results precede arguments 'was a commonplace for ancient mathematicians ... The Greeks did not think much of propositions they happened to hit upon in the deductive direction without having previously guessed them'.⁴⁷ Carl Friedrich Gauss, one of the most fertile mathematical minds of all time, remarked 'I have had my results for a long time; but I do not know yet how I am to arrive at them'. To pick two famous mathematicians out of many, Johann Euler, who was also an astronomer, stated that arithmetical theorems are 'discovered long before their truth has been confirmed by rigid demonstration'; and George Pólya that 'you have to guess a mathematical theorem before you prove it'. The philosopher of science and mathematics Imre Lakatos emphasised that science is effectively a *dynamic* process in which results are never final, unchanging 'nuggets' of truth.⁴⁸

Karin Knorr interviewed scientists about their work and found that when they described the origin of an innovative piece of research, they talked about having grasped a 'similarity between hitherto unrelated problems and contexts'.⁴⁹ In other words, they proceeded by analogy rather than analysis. It is no surprise, therefore, that it is often through images – metaphors – rather than supposed chains of logic, that scientists and mathematicians make their greatest discoveries. 'The words or the language, as they are written or spoken', wrote Einstein, 'do not seem to

play any role in my mechanism of thought. The psychical entities which seem to serve as elements in thought are certain signs and more or less clear images which can be “voluntarily” reproduced and combined ... The above mentioned elements are, in my case, of visual and some of muscular type.’⁵⁰ It is said that Kekulé seized the shape of the benzene ring, the foundation of organic chemistry, when the image of a snake biting its tail arose from the embers of his fire;⁵¹ Mendeleev saw the structure of the periodic table of the elements in a dream.⁵² The seminal mathematician Solomon Lefschetz

saw mathematics not as logic but as pictures. His insights were great, but his ‘proofs’ were almost always wrong.⁵³

Michael Faraday is one of the most influential scientists in history, who made hugely important advances in our understanding of magnetism and electricity. According to Helmholtz,

with quite a wonderful sagacity and intellectual precision, Faraday performed in his brain the work of a great mathematician without using a single mathematical formula ... it is in the highest degree astonishing to see what a large number of general theorems, the methodical deduction of which requires the highest powers of mathematical analysis, he found by a kind of intuition, with the security of instinct, without the help of a single mathematical formula.⁵⁴

Some people might be surprised to learn that Niels Bohr’s research notebooks contained only pictures and words, no mathematical formulae.⁵⁵ Heisenberg writes of Bohr, arguably the greatest physicist of the last century: ‘We could clearly sense that he had reached his results not so much by calculation and demonstration as by intuition and inspiration, and that he found it difficult to justify his findings before Göttingen’s famous school of mathematics’.⁵⁶

It is not, moreover, just that a few gifted geniuses who rock the foundations need imagination to make their discoveries. The whole enterprise of science as she is practised is dependent on imagination in

order to interpret what it is one is seeing. The problem is not that it is hard to rule out the human element, but that by attempting to rule it out – especially by ignoring the role of interpretation – we misrepresent the situation we describe. A particularly striking example is given by the economist Robert Chambers: 22 different studies of soil erosion in one catchment area in Sri Lanka yielded figures that differed by a factor of 8,000. ‘The scary part’, comments David Boyle, ‘is that all the figures were probably correct, but the one thing they failed to provide was objective information. For that you need interpretation, quality, imagination.’⁵⁷ Better still would be to accept that objective is a relative term, and that truth is, too: complex, multifaceted, rarely if ever single, never simple. Which, to repeat, since the point is so vital, does not for an instant imply giving up on it altogether.

In all science, moreover, chance plays as prominent a role as any method. Alexander Fleming’s chance discovery of the antibiotic applications of penicillin is too well known to need relating, but to take a few examples out of many from my own field, almost every treatment for bipolar disorder was discovered ‘by mistake’, not by scientific method. Lithium’s effect as a mood stabiliser was discovered indirectly: urea was initially thought to be a mood stabiliser (it is not), and it just happened that the lithium salt of urea was used. Later it was found that it was not the urea, but the lithium, that worked.⁵⁸ Another mood stabiliser, carbamazepine, was discovered during a search for antihistamines. Valproate was developed in Germany during the war as a butter substitute – it was used in pills as a diluent: it turned out that the diluent was what did the trick. Serendipity is the scientist’s friend; but it is a reciprocal relationship, as friendships are. As Pasteur put it, ‘in the field of observation chance favours only the prepared mind’.⁵⁹

Once again, this does not discredit science in any way: it shows, instead, what an exciting and humbling business science is. We *collaborate* with nature, and with fortune, pay attention and learn from her. We neither withdraw the human element, as the myth of the scientific method implies, nor *force* nature to our preconceived ends. With our limited understanding, and limited capacity to understand, that would be foolishness indeed. As Bacon, who is reputed to be the one who wanted to put Nature on the rack, nevertheless put it, ‘Nature to be commanded must be obeyed ... The

subtlety of Nature is greater many times over than the subtlety of the senses and understanding.’⁶⁰

So, far from being the impersonal, robotic business that the myth of the scientific method would imply, the actual practice of science in pursuit of truth is profoundly human. And at its core lies a human attribute to which no robot or computer could make any claim. As Max Planck put it:

Anybody who has been seriously engaged in scientific work of any kind realizes that over the entrance to the gates of the temple of science are written the words: *Ye must have faith*. It is a quality which the scientists cannot dispense with.⁶¹

SCIENCE'S AWARENESS OF ITS OWN LIMITS

In drawing attention to a widely held, but false, view of objectivity, to hidden assumptions that are blithely made, and to a misleading account of how science is practised, I am not, of course, suggesting that every scientist is in thrall to these misconceptions. Far from it. Many scientists are well aware of the inescapable limitations attending upon what they do and, consequently, of how qualified must be science's claims to truth and how false is any meta-claim that science has exclusive access to truth. Humility is not unknown in the scientific world.

Science has shown itself perfectly capable – at certain tipping points in its history – of recognising that it may be barking up the wrong tree or, at least, that the particular sort of barking it has been engaged in has run its course and that quite different trees merit attention. For example, it was physicists who definitively jettisoned the machine model around the time of the First World War, when their findings could no longer be made to fit the assumptions the model makes. The fundamental structure of the cosmos, they discovered, simply had few of the qualities of a machine. Revising the model has revealed further conundrums that require to be solved. Physics being the most philosophically sophisticated branch of science, it is only to be expected that it will recognise how very far it is from having all the answers, since the hallmark of a greater understanding is awareness of one's own limits. Promises from physics' more zealous exponents that a 'Theory of Everything' is just around the corner should be treated with caution: it has been just around the corner for over a century.

One of the most sharp-eyed observers of the current situation in physics is cosmologist and theoretical physicist Lee Smolin. 'Those scientists who work on the foundations of any given field', he points out, 'are fully aware that the building blocks are never as solid as their colleagues' – and, *a fortiori*, the general public – 'tend to believe.'⁶²

For example, to return to the question of how rooted in evidence science needs to be, but how hard a criterion that is, in practice, to fulfil, he comments on the idea of extra dimensions: 'in fact, neither theory nor experiment offers any evidence at all that extra dimensions exist.'⁶³ Neither is there any evidence whatever that there is an infinity of universes –

another popular theoretical gambit, driven by the desire to avoid the clearly unpalatable conclusion that intelligence might be intrinsic to the one universe of which we know something. It is another version of ‘anything goes’ (in an infinite number of universes, everything is as true as anything else), this time coming, alarmingly, from scientists who should know better.

My point is not here to argue that there are, or are not, a multitude of universes, something I am unqualified to do, but to suggest that the public idea of science as securely rooted in fact is a half-truth.

Of string theory, Smolin comments, ‘despite the absence of experimental support and precise formulation, the theory is believed by some of its adherents with a certainty that seems emotional rather than rational.’⁶⁴ Pouring cold water on the fervour, he quotes the physicist Brian Greene:

Even today, more than three decades after its initial articulation, most string practitioners believe we still don’t have a comprehensive answer to the rudimentary question, What is string theory?⁶⁵

This comes, not from someone out of touch with scientific thinking on the issue, but from the Professor of Physics and Co-Director of Columbia University’s Institute for ... Strings, Cosmology, and Astroparticle Physics.

I suspect Smolin may not be entirely impartial here; and certainly I can have no personal view on string theory, which, within the considerable limits of my understanding of it, is in some ways highly congenial to my philosophy that processes are more fundamental than particles. I have nothing to say against it. Behaving as if string theory were true helps to explain things otherwise not apparently explicable. But that is what we are doing: making an assumption, one that to many people is elegant and helpful, but is unproven and may be intrinsically incapable of proof other than the excellent Pragmatist one that it works better than alternatives. No-one has been, and maybe no-one ever will be, able to detect a string (or the existence of the six extra dimensions the equations of string theory require). My point is not about string theory: it is that science is, and must be, alive, provisional and uncertain, not, as many non-scientists are led to assume, laid out cold on a slab.

Smolin continues:

We must be careful to present the failures along with the successes. Indeed, being honest about failures is likely to help rather than hurt our cause ... In recent years, many books and magazine articles for the general public have described the amazing new ideas that theoretical physicists have been working on. Some of these chronicles have been less than careful about explaining just how far the new ideas are from both experimental test and mathematical proof.⁶⁶

In quantum mechanics the picture is considerably better, but even there clarity and certainty cannot be claimed, according to Anton Zeilinger and colleagues:

Quantum theory is based on a clear mathematical apparatus, has enormous significance for the natural sciences, enjoys phenomenal predictive success, and plays a critical role in modern technological developments. Yet, nearly 90 years after the theory's development, there is still no consensus in the scientific community regarding the interpretation of the theory's foundational building blocks.⁶⁷

Great scientists tend to be very cautious about the claims that can be made for science. J.B.S. Haldane's famous remark that the universe is probably not just queerer than we suppose, but queerer than we *can* suppose, puts its finger firmly on the point at issue. Humility of approach displays insight. 'How shallow, puny, and imperfect are efforts to sound the depths in the nature of things', wrote Whitehead. 'In philosophical discussion, the merest hint of dogmatic certainty as to finality of statement is an exhibition of folly.'⁶⁸

And, finally, there is an obvious point that still needs to be made despite its being so obvious. There are realms of human experience, vast realms of the reality that constitute 'the world' as human beings encounter it, that are beyond the methods of science to investigate in anything other than a trivial way. Erwin Schrödinger put his finger on it when he graphically described the process involved in trying to comprehend (rather than explain) the world in a scientific way, and what then ensued:

I actually do cut out my mind when I construct the real world around me. And I am not aware of this cutting out. And then I am very astonished that the scientific picture of the real world around me is very deficient. It gives a lot of factual information, puts all our experience in a magnificently consistent order, but it is ghastly silent about all and sundry that is really near to our heart, that really matters to us ... Science sometimes pretends to answer questions in these domains, but the answers are very often so silly that we are not inclined to take them seriously.⁶⁹

Some scientists have become rather famous through promoting their 'discovery' of the purposelessness of life. But science could never discover any such thing. According to its own assumption, its method excludes questions of teleology altogether. Science understandably does not find a purpose, because purpose is not something its way of thinking recognises. That is not a criticism of science *per se*. At most it is a criticism of a certain 'philosophy' of science, rarely critically examined, or even challenged; more generally it is a criticism of those who want to take the methodology of science into realms where it has no purchase on reality. When it comes to the really big questions – such as the nature, meaning or purpose of life, consciousness, time, love, energy, matter, beauty, truth or goodness – science encounters the limitations inherent in its dependence on models as the necessary means of proceeding, for in these cases there not only isn't an appropriate model, there can't be one, because each of them is completely *sui generis*. The ultimate nature of reality, as well as the origin of values, meaning and purpose in life, lie beyond the remit of science, though they continue to be of supreme importance for living. To quote Bertrand Russell: 'Almost all the questions of most interest to speculative minds are such as science cannot answer ... Science tells us what we can know, but what we can know is little, and if we forget how much we cannot know we become insensitive to many things of great importance.'⁷⁰

CONCLUSION

In conclusion, the point I wish to make – and I cannot emphasise it strongly enough – is that just because what we rightly take to be scientific truths are not ‘objective’ in the sense that nothing human, contingent and fallible enters into them, this does *not* mean they have no legitimate claim to be called true. Such a position would be trivial and absurd. My point is that truth is *never* objective in this, artificially limited, sense. But, important as it is to recognise that, it is every bit as important to validate science’s attempt to respond as fairly and fully to the reality with which it engages. Fairly, like fully, means inhabiting a number of points of view, not fruitlessly attempting to inhabit none. All knowledge whatsoever is contextual and contingent. The observer inevitably alters what is observed. Yes, OK. But that tells us about the nature of truth, not about the undiminished value of science.

I also want to emphasise that the scientific process cannot be free from assumptions, or values; that its advance requires imagination, as well as serendipity – not merely the stolid adherence to a procedure; and that it represents a rich creative process, always provisional, requiring breadth and depth of thinking, and that that is why we rightly value it so highly. Here again one sees the contrast between how the left hemisphere would conceive science and how the right hemisphere would do so, a subject I will explore further in the next two chapters. In science we need a balance between what *each* hemisphere provides, not just the contribution of one, be it left or right. However, there is no question that there is currently an imbalance. As Roger Sperry’s colleague Jerre Levy put it: ‘One gets the suspicion that 18 or so years of formal schooling in the sciences may functionally ablate the right hemisphere.’⁷¹

Bear in mind, moreover, that the left hemisphere is the manipulator: it presumes that the purpose of science is to help us exploit the world. In the Introduction, I quoted Erwin Schrödinger’s important words, from *Science and Humanism*, that the value of science lies in forming part of the knowledge humanity can bring to bear on the ultimate question, the question of Plotinus’: ‘who are we?’ That, of course, requires a much broader scope, more typical of the right hemisphere’s understanding.

Wendell Berry points out that ‘the modern university is organised to divide the disciplines; that universities pay little or no attention to the local and earthly effects of the work that is done in them; and that in the universities one discipline is rarely called upon to answer the questions that might be asked of it by another discipline.’⁷² These are serious problems, and I hope the path taken by this book will play a part in redressing them, even if only a little. But to address Plotinus’ question from within the discipline of science rather than the humanities, we would need especially to turn to the science of life. That forms the subject of the next chapter.

Plate 1[a] Lobes of the brain

Plate 1[b] · Diencephalon, basal ganglia and limbic system

Plate 1[c] · Prefrontal cortex and limbic system

Plate 1[d] · Optic pathways

Plate 2[a] · Superior longitudinal and uncinate fasciculi. See Chapter 6 et passim.

Plate 2[b] · Neural network of *Nematostella vectensis*. Two signal paths, Wnt and BNP, that are instrumental in the centralization of nerve cells in vertebrates, are already asymmetrically distributed in the nerve net of a sea anemone 700 million years old. See Chapter 1.

Plate 2[c] · Comparative anatomy of neocortex in mouse, monkey and man. The neocortex is shown in blue-green. See Chapter 1.

Plate 3[a] · Sagittal section of the brain of a dog and of a human brain (cc = corpus callosum; mb = midbrain; p = pons; m = medulla). Note that the relative size of the corpus callosum has diminished with cortical expansion. See Chapter 1.

Plate 3[b] Simulation of palinopsia/ akinetopsia. See Chapter 2.

Plate 4 · The Garden of Earthly Delights, by Hieronymus Bosch, oil on board, c 1505. Features in common with right hemisphere dysfunction include not merely hallucinatory transformations, harsh dislocations of bodily form, and an emphasis on sharp, penetrating elements, but the isolation of elements, a triumph of disjunction over flow, the rejection of natural harmony of form or colour, and the deluge of detail threatening to overwhelm our sense of the whole. It has been suggested that Bosch suffered from ergotism, a condition caused by eating rye affected by ergot mould, which was accompanied by hallucinations: LSD was first synthesised from ergot fungus. Whether or not this is the case, it is interesting that ergotism would appear to affect more particularly the right hemisphere of the brain (see Senter et al 1976). See Chapter 3.

Plate 5[a] · Hemiprosopometamorphopsia: representation of a patient's perception of faces. See Chapter 3.

Plate 5[b] · Head of a Woman, by Pablo Picasso, oil on canvas, 1960. 'Faces resembled the paintings of Picasso.' See Chapter 3.

Plate 6[a] · The Persistence of Memory, by Salvador Dalí, oil on canvas, 1931. Faces, in the left field of vision, melt away ‘like clocks in a Dali painting’. See Chapter 3.

Plate 6[b] The right temporoparietal junction in social interaction (from Decety & Lamm 2007). See Chapter 6.

Plate 7 · The top row shows a photograph of Otto Dix, and two self-portraits from before his RH stroke. The bottom row shows three self-portraits from the period after his stroke. By comparison these are sketchy – almost cartoon-like (cf Fig. 20, p 262); they lack vitality, and above all the impression of Dix's character, when compared with the pre-stroke drawings and the photograph. Note in particular that, in the last frame (f), the painting hand obtrudes in the painting and threatens to obscure the face. It also has six fingers, as did the hand in his last selfportrait with his granddaughter, Marcella. See Chapter 8; for supernumerary body-parts, see Chapter 4.

Plate 8 · Lovis Corinth suffered a RH stroke in 1911. Compare (top row) a portrait of his wife in 1910, and of a friend's daughter, Sophie Cassirer, in 1906, with (bottom row) a portrait of his wife in 1920, and of his own children in 1916 (oil on canvas, and graphite on paper).

Plate 9 • Lovis Corinth (continued). Compare, from before his stroke (top row), Laughing girl, 1883, and Black Othello, 1884, with, from after his stroke (bottom row), The beautiful Imperia, 1925, and Mrs Hedwig Berend, 1923 (oil on canvas, and graphite on paper). For discussion, see Chapter 8.

Plate 10[a] · The Puppetmaster (from Bethlem Royal Hospital Archive), anon, watercolour on paper. See Chapter 9.

Plate 10[b] · Self-portrait with Skeleton Arm, by Edvard Munch, lithograph, 1895. See Chapter 9.

Enlargements of The Maze, by William Kurelek

Plate 12[a] · Areas of significance for fluid intelligence. The areas of significance for fluid intelligence are illuminated; as will be seen, they lie almost exclusively in the right hemisphere of the brain (NB the right hemisphere, according to radiological convention, is on the viewer's left). (from Barbey, Colom, Paul et al 2014). See Chapter 7.

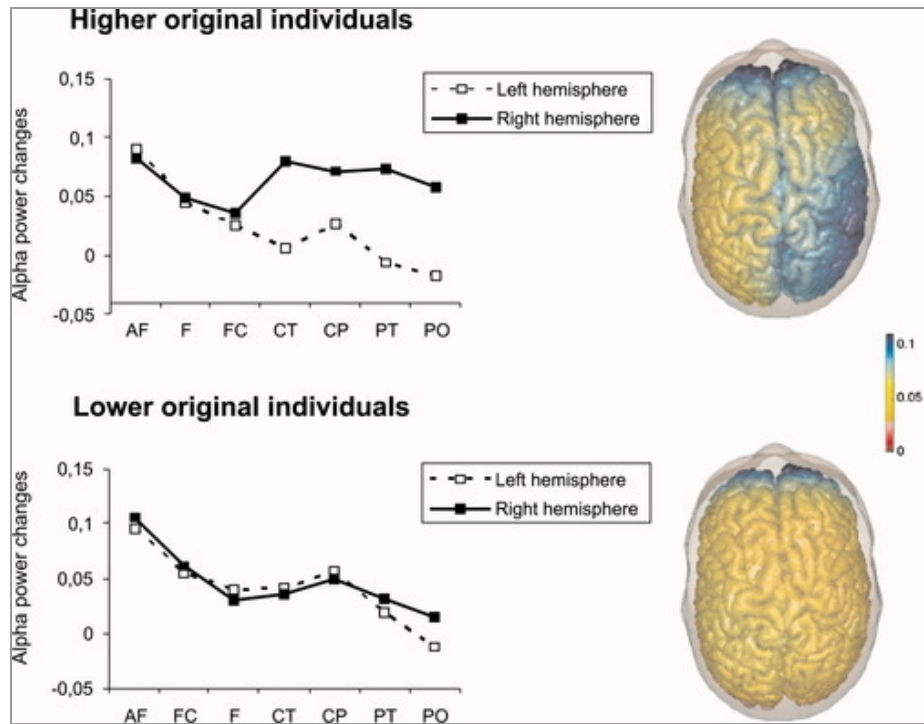

Plate 12[b] · Highly original subjects show stronger alpha power increases in the right posterior hemisphere; less original subjects show no hemisphere difference. (from Fink, Grabner, Benedek et al 2009). See Appendix 1.

Figure 1 THE NEW SIMPLE VIEW : EVERYTHING DOES EVERYTHING

Plate 13[a] · ‘Horror graph’ of the cross-signalling between just five intracellular signal transduction cascades: inhibitory flows in red, facilitatory flows in green (from Dumont, Pécasse & Maenhaut 2001). See Chapter 12.

Plate 13[b] · Eyes of a fly, a frog and a human. See Chapter 12.

Plates 13[c] & [d] · Norfolk Island pine and eagle feathers: note the precision of overall form observed by the needles of the pine and the barbs of each feather. See Chapter 12.

Plate 14 · Jacob's Ladder, by William Blake, pen, ink and watercolour, c 1799–1807. See Chapter 16.

*Plate 15 · La belle captive, by René Magritte, oil on canvas, 1948.
The glow of fire on an area within the frame suggests that this is
neither merely presence, nor merely representation, but, like glass,
a plane that we need to see through. See Chapter 16.*

*Plates 16[a] & [b] · The chequerboard illusion. The image on the
right shows, by the addition of a bar, that A and B are in fact the
same colour. See Chapter 17.*

Plate 16[c] · The Wason test (1). Each card has a number on one side, and a colour on the other. Which card(s) must be turned over to test the idea that if a card shows an even number on one face, then its opposite face is red? See Chapter 18.

Plate 16[d] · The Wason test (2). Each card has an age on one side, and a drink on the other. Which card(s) must be turned over to test the idea that if you are drinking alcohol then you must be over 18? See Chapter 18.

*Plate 16[e] · The Ebbinghaus illusion. Context alters perception:
the orange circle is the same size in each configuration. See
Chapter 19.*

THE SCIENCE OF LIFE: A STUDY IN LEFT HEMISPHERE CAPTURE

Movement is the cause of all life.

—*Leonardo da Vinci*¹

It is nonsense to conceive of nature as a static fact, even for an instant devoid of duration. There is no nature apart from transition, and there is no transition apart from temporal duration.

—*Alfred North Whitehead*²

For all bodies are in perpetual flux, like rivers, and parts are constantly entering into and leaving them.

—*Gottfried Wilhelm Leibniz*³

By changing, it remains the same.

—*Heraclitus*⁴

‘IN THE LIVING WORLD, AT LEAST,’ WRITES PHILOSOPHER OF SCIENCE JOHN Dupré, ‘a metaphysics of “things” is hard to sustain.’⁵ Nonetheless it would appear to be the only realm of science in which it still holds sway. While the thinking of physicists has been obliged to jettison many of its old

assumptions, the thinking of most biological scientists does not seem to have kept pace – which is odd, if only because most contemporary biologists seem to believe that biology should be reducible to physics. (I'd say that, while it could never be reduced to physics, it should certainly be compatible with physics.) It has, at least until very recently, been stuck in a mid-Victorian mechanistic vision that physics abandoned over a hundred years ago. Cognitive scientist Donald Hoffman considers this a problem (as do I):

Not only are they ignoring the progress in fundamental physics, they are often explicit about it. They'll say openly that quantum physics is not relevant to the aspects of brain function that are causally involved in consciousness ... They don't avail themselves of the incredible insights and breakthroughs that physics has made. Those insights are out there for us to use, and yet my field says, 'We'll stick with Newton, thank you. We'll stay 300 years behind in our physics.'⁶

The problem is not just that biology has not availed itself of the insights of quantum physics. It's that its dogged adherence to the Newtonian mechanistic model persists in the teeth of the evidence of its incompatibility with the phenomena it is trying to explain. It is an egregious instance, I would suggest, of the sort of thing we have seen before when the left hemisphere insists that its re-presentations provide an adequate and complete account of reality – that a porcupine is a monkey because that's what the theory tells us. And it alerts us to the need to handle science's claims to truth with care.

Please don't get me wrong. I have nothing but respect and admiration for the ingenuity and hard work of my colleagues in the life sciences, and am exhilarated by the ever-growing body of knowledge about the natural world. It manifestly proves itself to be useful in myriad ways and, fairly obviously, my thinking too depends heavily on the broad reliability of recent scientific evidence about the brain and mind. Nonetheless, there is a problem.

Science's view of the world is always shaped by the philosophy it happens to adopt, whether consciously or (more usually) unconsciously. For physicists, as we have seen, it is more or less impossible to avoid

confronting philosophical issues head on. For biologists, however, confrontation with reality is tempered by the nature of their subject matter, which is more forgiving of a fudge. The evolutionary biologist and palaeontologist George Gaylord Simpson remarked that ‘not many biologists are given to exploring the philosophical implications of their science.’⁷ More trenchantly, the theoretical biologist and philosopher Joseph Henry Woodger wrote in 1929 that

physiologists in general never trouble themselves about such things because they suppose themselves to be above ‘metaphysics’ when in fact they are only a very little above it – being up to the neck in it.⁸

As David Bohm commented in the 1960s, it is an odd fact that, just when physics was moving away from mechanism, biology and psychology were moving closer to it. ‘If the trend continues’, he wrote, ‘scientists will be regarding living and intelligent beings as mechanical, while they suppose that inanimate matter is too complex and subtle to fit into the limited categories of mechanism.’⁹ He was not mistaken.

Nonetheless, in the first half of the twentieth century, many philosophically minded biologists, including such eminent British figures as John Scott Haldane and his better-known son, J.B.S. Haldane, as well as Conrad Hal Waddington, moved decisively, like the physicists, away from the machine model. Less renowned, largely by his own choice, but no less distinguished, was Ludwig von Bertalanffy, the great Austrian biologist and polymath who originated general system theory. In 1933 he wrote: ‘we cannot speak of a machine “theory” of the organism, but at most of a machine fiction’.¹⁰

Despite this encouraging development, a more or less abrupt reversion to the seventeenth-century Cartesian model came over the life sciences with the rise of molecular biology, and its language of ‘programmes’, ‘codes’, and so forth, in the twentieth century’s second half. According to Carl Woese, writing in 2004, ‘biology today is little more than an engineering discipline’.¹¹ And Woese was no embittered outsider. His pioneering work revolutionised mainstream biology; he was one of the most influential and widely honoured microbiologists of all time, described by a colleague as

having 'done more for biology writ large than any biologist in history, including Darwin'.¹² But he was disturbed by what he saw.

BIOLOGY AND MACHINES: A MISMATCH OF LANGUAGE

We now live in a world in which everything, including the human brain, is considered to be understandable in the same way – at a hugely different level of complexity, of course, but still in the same way – that we understand a pop-up toaster. ‘Before we can fully understand how our brains work, we need to understand how the parts work’, says Francis Collins, the director of the US National Institutes of Health.¹³ Reasonable enough, you may say – if you assume that ‘fully understanding how our brains work’ is something any scientist should even be talking about. But enquiring after how the ‘parts work’, already imports a host of assumptions, as we have seen. The answers one gets from Nature depend on how one frames the question.

‘There is little doubt about the biologist’s declared obsession with mechanisms of every sort’, writes Stephen Talbott, a philosopher of biology; these include widespread references to

‘genetic mechanisms’, ‘epigenetic mechanisms’, ‘regulatory mechanisms’, ‘signalling mechanisms’, ‘oncogenic mechanisms’, ‘immune mechanisms’, ‘circadian clock mechanisms’, ‘DNA repair mechanisms’, ‘RNA splicing mechanisms’, and even ‘molecular mechanisms of plasticity’ ... no cellular entity or process is exempt; everything has been or will be baptised a ‘mechanism’ ... The odd thing is that I have yet to find a single technical paper in molecular biology whose author thought it necessary to define *mechanism* or any of the related terms.¹⁴

Yet what is even odder is that, having made this ritual obeisance to the machine, biologists carry on to describe the organism in language wholly incompatible with mechanism, a language that would be neither required, nor permitted, in chemistry or physics.

It will no doubt be said by some that such language is just a *façon de parler*, such as when I say that my car engine ‘labours’, or ‘struggles’ to get up the hill in third gear. But that is not an adequate response to the sheer ubiquity, scope and inescapability of such language – or, more significantly,

the nature of the phenomena it is called on to describe. As Whitehead pointed out, 'it is notable that no biological science has been able to express itself apart from phraseology which is meaningless unless it refers to ideals proper to the organism in question.'¹⁵

I would suggest that there are broadly six features that stand out in the language inevitably used by biologists, rather than by physicists or chemists, time and time again, year after year, decade after decade, century after century, Darwin and Dawkins included – language used to describe what they actually see, but which stands in blatant contradiction to the metaphor of the machine. What are they? References to (1) *actively co-ordinated processes*, expressing a sense of (2) *wholeness*, inextricably linked with (3) *values*, (4) *meaning* and (5) *purpose* – each leading separately and together, to the phenomenon of (6) *self-realisation*. None of these get to be applied to my car.

Let me give some examples. First, 'actively co-ordinated processes'. Apart from, directly, 'co-ordinating' functions, processes, developments, and so on, elements of the organism are said to 'regulate', 'control', 'guide', 'induce', 'impose' order on, and at times 'disorder', 'arrange', 'restructure themselves', 'develop', 'adapt', 'respond', 'attempt', 'instigate', 'stimulate', 'inhibit', 'suppress', 'transmit', and 'receive' or 'extract' information from other elements of the whole.

Then 'wholeness'. References to 'rhythm' and 'harmony' aside, elements of the organism are said to 'inherit' information, modes of action or modes of expression, from other organisms from which they are neither structurally nor functionally wholly distinct; they are said to 'exhibit plasticity', involving transformation not of a part or parts, but of the whole; they 'modify themselves', 'integrate', 'unify', 'co-ordinate', 'organise', and 'interpret' *contextually*, that is to say, with regard to the whole organism, not just a part.

Or 'values'. Organisms are normative. They exhibit what is termed 'normal', or 'proper', development; they may exhibit 'errors' or 'mishaps'; 'suffer injury'; engage in 'healing'; attempt 'correction', or instigate 'repair'; perform actions in a 'timely' fashion (or not); exhibit 'aberrant' or 'corrective' reactions; promote 'health', suffer 'disease' and eventually die.

What about 'meaning'? How else to understand the talk of 'giving and receiving information', the 'recognising' and 'interpreting' of signals, the 'distinguishing' of 'relevant' from 'irrelevant' information, the 'adoption',

‘erasing’ or ‘extraction’ of a code, the ability to ‘communicate’, ‘respond’, exhibit ‘intention’, or ‘directed activity’, and the ability to – in some way we do not understand – ‘sense’ that something, some disturbance, say, is present. For example, an influential paper refers, not inappropriately, to ‘decision-making’ by single cell bacteria.¹⁶ I will come onto such decision-making by single cells in due course.

And ‘purpose’? However you may toss her out with a pitchfork, as Horace said, nature hurries back in by the door;¹⁷ and it is impossible to describe the living world at any level without references to aims, purposes or drives. Biological molecular interactions have ‘targets’, ‘recruit’ other molecules for an end, ‘assist’ in processes, ‘aim’ at certain outcomes, have ‘goals’ and ‘achieve tasks’: they act ‘in order to’ secure certain ends by certain means. Single cells are constantly described as ‘behaving’ in certain ways.

Each of these five characteristics singly – and *a fortiori* together – suggests the sixth: a process of ‘self-realisation’. The organism *as a whole* acts in a *co-ordinated* fashion to create and respond to *meaning* in the pursuit of *value-laden goals*, whereby it is fully realised and fulfilled as an organism. ‘Living cells do not operate blindly’, writes James Shapiro, professor in the Department of Biochemistry and Molecular Biology at the University of Chicago: ‘life requires cognition at all levels.’¹⁸

We humans, obviously, exhibit these same qualities, behaviours and purposes. It is conventionally assumed that when we describe them in non-human organisms, we are simply projecting our own onto them. But why? Even in our case, it almost all goes on effortlessly outside of awareness: being aware consciously is not a requirement at any point. The array of descriptors I have just outlined is the same as those we would use in describing a dog’s behaviour at every level, and that includes those of which it is and is not aware, those under its conscious control and those that are not, those in its brain and those in its tail. And the same, *mutatis mutandis*, operates in the case of a frog or a bird. When we see cells within the bird – or the frog or the dog – exhibit the same characteristics as the creature as a whole, why should we make an arbitrary distinction at some level? On what principle and at what point?

You might well be tempted to think that language is one thing, but the actual biological findings another. If you are, read on.

The model of a mechanism, it seems, presents a problem in describing what biologists actually see, otherwise machine language would suffice. And this very fact, in turn, according to Talbott,

immediately raises a suspicion of vitalism in the minds of many scientists. Who, after all, is this organism? And by what special powers does it 'regulate', 'integrate', 'respond', and 'communicate'? Bear in mind, however, that these questions press just as urgently upon the conventional molecular biologist as on the suspected vitalist. After all, the loaded terminology comes straight from the laboratory, where researchers are trying to make sense of what they see ... a lot of experiment and observation has led to this language.¹⁹

If descriptions of organisms cannot avoid the suggestion of meaning, I would like to suggest that that is not because of the inevitably sloppy thinking of generations of highly intelligent, dedicated and observant biologists, but because they are onto something. Organisms are said to perceive or know things because they do: they are said to respond appropriately to changing circumstances, because that is exactly what happens.

Just so that you don't think that speaking of cells as being able to sense, perceive or know is something that no serious biologist could entertain, let me quote Barbara McClintock, the founder of the field of cytogenetics, from her Nobel Prize acceptance speech in 1984:

some *sensing* mechanism must be present ... to *alert* the cell to imminent *danger*... the conclusion seems inescapable that cells are able to *sense* the presence in their nuclei of ruptured ends of chromosomes and then to activate a mechanism that will bring together and then unite these ends, one with another ... the *sensing* devices and the signals that initiate these adjustments are beyond our present ability to fathom. A goal for the future would be to determine the extent of *knowledge* the cell has of itself and how it utilises this knowledge in a '*thoughtful*' manner when challenged ...

We know nothing, however, about how the cell *senses* danger and instigates responses to it that often are truly remarkable.²⁰

Responses that are, as well, sometimes wholly original and in no way pre-programmed – a marker of intelligent response – as we shall see.

Put simply, if you ask biologists explicitly, they will, with a few exceptions, cleave to the machine model; but when you listen to what they are saying, implicitly they abjure it. Yet despite this manifest dissonance at the core of biology today, the machine model is the one that is peddled to children, students, and the general public wishing to learn more about biology, the fascinating study of the nature of life. Any suggestion otherwise is pounced on as evidence of heresy and denounced.

FROM ROBOTS TO COMPUTERS – BYPASSING ALL THAT MATTERS ON THE WAY

‘Today, the genetic program is everywhere’, writes philosopher of biology Daniel Nicholson:

It appears in biology textbooks, such as when organisms are said to be ‘governed by the laws of physics and chemistry as well as a genetic program’.²¹ It is present in the technical literature, such as when claims are made that ‘a cell can be seen as a computer (a machine expressing a program)’.²² And it is also prominently featured in works of popular science. In one of the most memorable phrases of Richard Dawkins’ hugely influential *The Selfish Gene*, organisms are described as ‘survival machines – robot vehicles blindly programmed to preserve the selfish molecules known as genes’.²³ Even some philosophers of biology, who should probably know better, have enthusiastically defended the reality of the genetic program.²⁴

And Nicholson adverts to an egregious example:

The genes program the embryo in the same way that the hardware in an automobile assembly plant’s robots’ central processing units realize a program that enable [*sic*] them to weld chassis without human supervision and more accurately than any human can perform this task. This latter thesis requires no philosophical defence. It is obvious to anyone who examines the available accounts of the embryological development of, say, the *Drosophila* [fruit fly].²⁵

There are many problems with this (and some of them, as I will show, are illuminated precisely by examining the development of *Drosophila*). ‘In reality’, writes Nicholson, ‘DNA is only functional when it is embedded in the context of an already present, intricately organized cell’:

It is only in the presence of a pre-existing cellular apparatus that any talk of ‘gene action’ can even make sense. And what is more, the origin of that cellular apparatus cannot be traced back to the genes ... many cellular structures such as membrane-bound organelles, as well as the plasma membrane itself, are the only template for their own replication; that is, they are the only source of ‘information’ for their own three-dimensional structure.²⁶

And the distinguished Harvard geneticist Richard Lewontin comments:

Genes are said to be ‘self-replicating’, they engage in ‘gene action’, they ‘make’ proteins, they are ‘turned on’ or ‘turned off’ by ‘regulatory’ DNA. But none of this is true ... Genes ‘do’ nothing, they ‘make’ nothing ... DNA is among the most inert and nonreactive of organic molecules.²⁷

Indeed, it’s not just what genes don’t ‘do’: it’s what they don’t ‘know’. There is not anything like the necessary set of instructions in them. ‘It is commonly stated that the genome incorporates a *Bauplan*, an architectural plan or blueprint of the body’, writes immunologist Werner Müller in his classic textbook, *Developmental Biology*. ‘Actually, this is not the case: the genome is not a sketch or design of the finished body.’²⁸

Many, many other elements than the genotype go to make the phenotype – the organism we can see. As well as DNA, it is obvious that chromatin, RNA, cellular signalling pathways, selective modes of protein translation, and the membrane architecture of the cell all contribute, for a start. The proper response to the news that we share 98–99% of our genes with a chimpanzee, or 50% with a banana, is not that we must be barely distinguishable from chimps and not far from being bananas, but that the determining role of genes *as such* is more limited than we thought.²⁹

Please note, I am not for one moment denying the importance of heredity: it is very important indeed. I am merely suggesting that it is far more complex than we are led to believe. You cannot consider *genes* in isolation from many other aspects of the organism. ‘Genetic change’, writes Shapiro, himself a geneticist, ‘is almost always the result of cellular action on the genome.’³⁰ Not, then, solely, or even principally, the action of the

genome on the *cell*. But more importantly, heredity is more than genetics: it passes from whole organism to whole organism, not just via DNA – exactly how, we do not know.

It is quite impossible for genes to ‘programme’ the making of an embryo. For a start, there is nowhere near enough information contained in genes. Consider the human brain, never mind the whole human body. With an estimated 100 billion neurones, a quarter of a million of them are created on average during every *minute* of the nine months of gestation, at times more. Each of these neurones, needless to say, must then make thousands of connexions with other neurones, and all this must end up in a minutely specific, hugely complex architecture with every part of the whole in exactly its required location. Where was that information in the ‘programme’ that DNA is said to enshrine?

We have an estimated 26,000–30,000 genes (what counts as a gene is not a cut and dried matter, but to a certain extent a human convention, and involves elements of judgment). But a blind, millimetre-long roundworm, *Cænorhabditis elegans*, with only 959 cells in total already has over 19,000. Indeed the pea aphid has 34,600 genes; and *Daphnia pulex*, a water flea common in lakes and ponds around the world, and about the size of a full stop on this page, has 39,000.³¹ A species of amoeba has the largest recorded genome, 670 billion base pairs, roughly 200 times the size of the human genome.³²

And then, only a tiny fraction, about 2%, of our DNA consists of exons, those regions of a gene that actually contain the information required to encode a protein.³³ With 1,200,000 proteins being produced, it is quite clear that any one gene must code for many different proteins, depending on the context.³⁴ The ‘same’ DNA proteins, with the same amino acid sequences, can, in different environments, ‘be viewed as totally different molecules’, with distinct physical and chemical properties.³⁵ Protein synthesis is subject to epigenetic influences to such an extent that the same gene ‘blueprint’ can create 2,000 or more variations.³⁶ Epigenetic changes are those that are acquired during the lifetime of individuals – from particular experience – and alter gene expression in any one of a number of ways in the next generation. This means that evolution is much smarter than often portrayed. It doesn’t have to wait millions of years, drumming its fingers, waiting for randomness to catch up with experience.³⁷

The other 98% of the genome used to be referred to as junk DNA, because it seemed meaningless, consisting of endlessly repeated sequences that code for nothing. These sequences are no longer considered junk, simply by deduction from the fact that they make a difference – but how they make a difference is not yet known.

Indeed, what is a gene? According to the geneticist Rick Young at MIT, when he first started teaching in the mid-1980s it took him about two hours to teach raw undergraduates what a gene was and how it worked. Today he and his colleagues need three months of lectures to convey the concept of the gene to graduates. Karola Stotz and Paul Griffiths collected 14 atypical but real genetic arrangements and asked biologists to decide whether each represents one, or more than one, gene.³⁸ For example, in one case a protein is assembled when four different RNA molecules, made from DNA scattered over 40,000 base pairs, are assembled into one transcript. They found that though the biologists were fairly evenly split, ‘hardly any confess that they don’t know’.³⁹ Instead of discrete genes mass-producing identical RNA transcripts, ‘a teeming mass of transcription’ converts many segments of the genome into multiple RNA ribbons of differing lengths. Some of these transcripts come from regions of DNA previously thought not to contain protein-coding genes. The genome contains many overlapping transcripts, genes within genes, and even genes that seem to be controlled by regulatory regions from another chromosome.⁴⁰ ‘Discrete genes are starting to vanish’, according to Roderic Guigó, Director of the European Research Council’s Centre for Genomic Regulation.⁴¹

In sum, the extraordinary fidelity and robustness of organismal development is not attributable to a programme, an algorithmic sequence of predetermined steps that must be carried out in a certain order, as with a machine. The cell is constantly monitoring, promoting, inhibiting (including, as necessary, inhibiting its inhibitors), repairing, splicing and rewriting DNA. Each ‘step’, as we are accustomed to think of it, is not computed from the immediately preceding one, but is part of a process in which information comes from many sources, a process that can’t properly be thought of as decomposable into steps at all. The development of an embryo requires an unimaginably intricate series of local interactions, not specifiable by a single global control mechanism. ‘The genetic program does not explain development’, writes Nicholson; ‘it merely black boxes it’:

Embryogenesis is much too complex and much too reliable in its outcome to be specified by a program. If development were a program, the fertilized egg (not to mention the genome) would never succeed in computing its output.⁴²

That a purely deterministic programme would be prone to error might seem counterintuitive; but when one takes into account the degrees of freedom involved in the process when compared with the rigidity of a manmade machine, and the degree of complexity involved in constructing an embryo, it becomes apparent. Dupré explains why any such deterministic programme would fail, using an analogy. He points out that the precision with which fantastically complex processes are carried out, often by different paths on different occasions and under different circumstances, necessitates an overall goal, not a set of deterministic steps – which would be far too likely to go wrong:

If I ask someone to go to the shop and buy me a loaf of bread, and they agree, I am fairly confident that the outcome will be as I intend. If I provide a deterministic programme – take 12 paces north-west, raise hand, turn knob, push, etc, there are too many unanticipated interventions that can derail the process for me to have much hope of success. Teleology is much better than deterministic causation at getting things done, and development is much too reliable to be seen as anything but teleological.⁴³

I will return to teleology in due course. Certainly, the levels of accuracy achieved in the replication of the genome are awe-inspiring and attest to a complex and active process of monitoring of the genome by the cell, resulting in a three stage programme: (i) selection of the correct DNA nucleotide by the replicative DNA polymerase; (ii) removal of any mis-inserted nucleotides by a proofreading activity associated with the polymerase; and (iii) post-replicative correction of polymerase errors that have escaped proofreading by the DNA mismatch repair system.⁴⁴ This reduces errors in the transcription of an entire genome of 3 billion base pairs from a few million to less than 1. This is achieved not by the genome but by the *system as a whole* operating at several levels. According to the

biologist Denis Noble, ‘the order at the molecular (DNA) level is actually imposed by higher level constraints’.⁴⁵ Top-down causation is not supposed to happen in the reductionist model.

Nicholson speaks of the genetic program not explaining development, but merely ‘black boxing’ it. Current biology is littered with such ‘black boxes’. Take the concept of ‘emergence’: it is a perfectly useful term for pointing to what Bergson called creative evolution – the extraordinary coming into being of completely novel qualities as a system grows in complexity. The problem arises when we use it not just to point, but as though offering an explanation. This is like Molière’s doctor grandly explaining that opium makes one sleep because of its ‘dormitive properties’. Speaking gravely of emergence is fine as long as you do not imagine you have explained anything thereby. You have merely sidestepped another problem for reductionism. The rabbit ‘just did’ emerge from the hat. What was to be explained has just been rephrased, and *voilà* – another mystery solved.

The idea that the development of an individual organism is the unfolding or execution of a genetic program suggests a kind of simultaneous myopia and tunnel vision, lacking both depth and breadth of insight. As Levins and Lewontin point out,

The organism is the consequence of a historical process that goes on from the moment of conception until the moment of death; at every moment gene, environment, chance, and the organism as a whole are all participating ... Natural selection is not a consequence of how well the organism solves a set of fixed problems posed by the environment; on the contrary, the environment and the organisms actively co-determine each other.⁴⁶

The shape that an organism takes emerges from its own physiological states, as much as from genes, and these are as much under the influence of apparently ‘foreign’ organisms as of the organism itself. Referring to the impossibility of distinguishing neatly the intestines from their exceedingly numerous and complex inhabitants, biologist J Scott Turner points out that ‘it is physiology more than genetics that forges the designed gut.’⁴⁷

Even within the organism, genes are only one part of a bigger picture. The cell context – which so radically changes the way in which DNA will act, and which itself reads, interprets, and deploys, according to need, whatever there is in the DNA to read – is not itself specified by the DNA. ⁴⁸ The assumption that it would be like Chomsky asserting nonsensically that language springs from the child's brain without interaction with the environment. Philosopher of science Richard Burian writes:

Without knowing an enormous amount about the contexts in which a sequence and its products are placed – contexts that vary enormously in ways that cannot be predicted from complete knowledge of the genome – there is, in general, no determinate answer to the question, 'What does this sequence of nucleotides do for this organism?' Thus, if one tries to proceed strictly from the genome up, one cannot predict, in general, what effects sequence-identified genes will have on the organism and how they will affect its fitness. ⁴⁹

DNA is itself a complex that is twisted in three-dimensions in a way so intricate, and economic in achieving multiple ends simultaneously, that it almost defies belief, so as to promote, bring together, or alternatively shelter from contact, regions of the molecule and their encoding capacity. The structure and its manipulation are at least as informative as the string of DNA itself. The molecule is a three-dimensional entity, not just an abstract two-dimensional string of symbols such as a computer might read, a fact which tends to be overlooked when speaking of 'code'.

The cell nucleus, which is around six millionths of a metre in diameter, contains two metres of DNA, a feat which is 'geometrically equivalent to packing 40 km (24 miles) of extremely fine thread into a tennis ball.' ⁵⁰ That's not all, since the 46 separate chromosomes (each averaging, if we continue the analogy, the equivalent of over half a mile long), have to be kept distinct and functional, not hopelessly entangled.

Enzymes known as topoisomerases, whose task is to help resolve complexities in the over-winding or under-winding of the chromosome, demonstrate 'a spatial insight and dexterity that might amaze those of us

who have struggled to sort out tangled masses of thread’, comments Talbott. He continues:

these enzymes manage to make just the right local cuts to the strands in order to relieve strain, allow necessary movement of genes or regions of the chromosome, and prevent a hopeless mass of knots. Some topoisomerases cut just one strand of the double helix, allow it to wind or unwind around the other strand, and then reconnect the severed ends. This alters the supercoiling of the DNA. Other topoisomerases cut both strands, pass a loop of the chromosome through the gap thus created, and then seal the gap again. (Imagine trying this with miles of string crammed into a tennis ball!) I don’t think anyone would claim to have the faintest idea how this is actually managed in a meaningful, overall, contextual sense, although great and fruitful efforts are being made to analyse isolated local forces and ‘mechanisms’.⁵¹

Don’t forget that this is not something that DNA itself can programme: it depends on the interaction of a large number of factors. Even then, according to a genetics research group at Holland’s Hubrecht Institute,

not only active, but also inactive, genomic regions can transiently interact over large distances with many loci in the nuclear space. The data strongly suggest that each DNA segment has its own preferred set of interactions. This implies that it is impossible to predict the long-range interaction partners of a given DNA locus without knowing the characteristics of its neighbouring segments and, by extrapolation, the whole chromosome.⁵²

Note, the *whole* chromosome: and not only that, but the *whole* cell. And ultimately the whole organism. None of this is reminiscent of how a machine works, nor is any of a whole bunch of factors I will now come on to consider.

In doing so, I have been enormously inspired by, and am greatly indebted to, the illuminating work of philosophers of science John Dupré and Daniel Nicholson – especially, but by no means only, by their edition of

a collection of papers by over 20 scientists and philosophers, the most thorough examination of processual philosophy in relation to biology to date, *Everything Flows: Towards a Processual Philosophy of Biology*, which the editors generously allowed me to read ahead of publication.^{[53](#)}

WHY ORGANISMS ARE NOT MACHINES

1. On-off

First, a machine is static until switched on, and may be switched off without ceasing to exist. Organisms, as Nicholson points out, much like waterfalls or tornadoes, do not have an off switch.⁵⁴ The very existence of an organism is, from beginning to end, one unceasing flow of matter and energy. For it to stop, even for an instant, would mean immediate death. As J.B.S. Haldane put it, using the image of fire – pure energy – rather than water, ‘a flame is like an animal in that you cannot stop it, examine the parts, and start it again, like a machine. Change is part of its very being.’⁵⁵ As he hints, analysis – examining its supposed ‘parts’ – would stop it and kill it. Yet the biologist endlessly, and for some purposes necessarily, relies on taking slices from the seamless flow of life. Just consider the conventional anatomical techniques (anatomy, the study of living form, literally means ‘cutting up’) for examining nature: dissecting, slicing, desiccating, pickling, staining, fixing, and freezing, not to mention vivisection.⁵⁶ Organisms may be taken apart, but they are not put together; they are not made –they become. And such entities as we can identify (genes, molecules) cannot take precedence over the relationships which *go to constitute them*.

In biology all is becoming, never just being:

in the biological world, at least – activity and being necessarily presuppose one another. Being is neither ontologically nor temporally prior to activity, as the very existence of living beings is only possible by means of continuous activity.⁵⁷

No machine model can make sense of this, since a machine must be built before it can be set in motion. This alone should alert us to its misleading nature. The machine, the thing, takes priority over the process: it comes first in time, and its existence grounds what it does. For living beings – perhaps they should be called living ‘becomings’ – this is not the case:

they are what they do, and come into being through their very movement. In this they are like streams that flow. Their being, their form, their becoming, is their movement; and their movement is their being.

2. Motion vs stasis

This leads seamlessly to the next obvious distinction. What has to be explained about a machine is how it changes at all. This is because it is a system that exists close to dynamic equilibrium. When power is applied, one otherwise static and self-contained component transmits energy to another static and self-contained component, and so on, in a linear chain. Then it is switched off, and it returns to equilibrium, where it can remain indefinitely.

In an organism, by contrast, what has to be explained is, not how it changes, but how it *remains stable*, despite constant change on an unimaginable scale. The stable continuance of a stream is owed to change. It depends on the flow of water molecules through it, entering and passing on elsewhere, and if the water ever stopped steadily flowing and replacing itself the stream would cease to exist. In this way, as Nicholson points out, the idea of an organism as a stream of life rather than a machine captures two essential and complementary elements: ‘the continuous exchange of matter that defines metabolism on the one hand, and the stability of form that is maintained in spite of it on the other.’⁵⁸

If we pay attention to what is disclosed by biological organisms, we cannot but see process and flow at its core. ‘Whatever else organisms may be, what cannot be denied at an ontological level is that they are stable metabolic flows of energy and matter.’⁵⁹ We know this intuitively. Most of the cells in your body were not there a few years ago: the form of the flow has persisted, but its original substance has utterly vanished. As the German poet Novalis observed in the late eighteenth century, ‘there is no doubt that our body is a moulded river’.⁶⁰ But this is not an intuition only. It is the best metaphor we have for the proper physiological understanding of living tissue. John Scott Haldane saw organisms as highly dynamic eddies of matter, which nonetheless had the power to remain stable over time – not things, but stabilised *processes*: ‘they are constantly taking up and giving

off material of many sorts, and their “structure” is nothing but the appearance taken by this flow of material through them.’⁶¹

Structure is the static element we illegitimately extrapolate from the flow of time. Individual organisms, and the evolutionary process in which they inhere, are *extended* in time – not a sequence of timeless structures, without extension, that replace one another. Structure is function once time has been excluded; function is structure once included in time.⁶²

Moreover, in as much as the organism can be said to have ‘fixed’ structures at all, they are themselves as much the *result* of flow, as the *cause* of it. Biologist Craig Holdrege gives this thought-provoking example, from human foetal development:

Before the heart has developed walls (septa) separating the four chambers from each other, the blood already flows in two distinct ‘currents’ through the heart. The blood flowing through the right and left sides of the heart do not mix, but stream and loop by each other, just as two currents in a body of water. In the ‘still water zone’ between the two currents, the septum dividing the two chambers forms. Thus the movement of the blood gives the parameters for the inner differentiation of the heart, just as the looping heart redirects the flow of blood.⁶³

Above I mentioned that change in a living organism takes place on an unimaginable scale. Let me give some idea of that scale. There are an estimated 37.2 trillion cells in the human body.⁶⁴ Each one of these cells performs many millions of complex reactions every *second*.⁶⁵ In doing so the cell does not act atomistically but within complex feedback systems with other cells. Biological enzymes promote extraordinary rates of change. In the absence of catalytic enzymes, the decarboxylation of amino acids would proceed with a typical half-life of about a billion years: in the presence of enzymes these half-lives are reduced to less than a thousandth of a second.⁶⁶ And a single molecule such as carbonic anhydrase – of which the body contains unimaginable numbers – can catalyse upwards of a million reactions per second.⁶⁷ Each protein may combine with ‘several hundred different modifier molecules, leading to practically infinite combinatorial possibilities’ and each ‘protein itself is an infinitesimal point

in the vast heaving and churning molecular sea of continual exchange that is the cell'.⁶⁸

One research team writes that in an organism we see a collaborative process that can be 'pictured as a table around which decision-makers debate a question and respond collectively to information put to them.'⁶⁹ But if that is the case, we must remember that, as Talbott points out,

the collaborative process mentioned above involves not just one table with 'negotiators' gathered around it, but countless tables with countless participants, and with messages flying back and forth in countless patterns as countless 'decisions' are made in a manner somehow subordinated to the unity and multidimensioned interests of the organism as a whole.⁷⁰

The human organism, it is clear, exists in a state of stable, patterned flux that we cannot even begin to conceive.

All living things metabolise, that is to say exist in a constant energetic exchange with their surroundings. The word 'metabolism', from Greek *metabolē*, means simply 'change'. Homeostasis, growth, and reproduction are the three most fundamental characteristics of cells and all living things – and they are all processes.⁷¹ 'One decisive reason for taking organisms to be processes', writes Dupré, is that they are

open systems that must constantly exchange energy and matter with their surroundings in order to keep themselves far from equilibrium. The persistence of an organism is dependent on its ability continuously to maintain a low-entropic 'steady state' in which there is a perfectly balanced import and export of materials. When this exchange ceases, the steady state is irretrievably lost and the organism succumbs to equilibrium, resulting in death ... You can leave your typewriter in an empty loft and return a decade later and start using it again. But if you accidentally leave your hamster in the loft, you will not have a hamster for very long.⁷²

At the cellular level, Dupré points out, 'the persistence of the human organism over the life cycle requires an almost inconceivably precise

balance of division, differentiation and destruction of cells.’⁷³ And at the molecular level, according to biochemist Ross Stein, proteins are not inert, but ‘dynamic entities that negotiate complex energy landscapes’.⁷⁴ Biochemistry, the chemistry of life, is endlessly dynamic, changing, creating, repairing, transforming. ‘The great challenge for the life sciences today’, writes Shapiro,

is to understand how all the regulatory processes and control circuits operate to make indescribably complex reproductive, repair and morphogenetic processes come out right in the face of changing circumstances.⁷⁵

To the left hemisphere’s linear habit of mind, and its predilection for ‘things’, there is something paradoxical about stability depending on change. But the joint action of two forces tending to counteract one another is one of the best recipes for stability, found throughout the natural world: it is the essence of homeostasis.⁷⁶ Examples are everywhere in animal and human bodies, in the regulation of temperature, blood pressure, muscle tone, hydration, cell renewal, and many, many other equilibria, which are stable because they are dynamic, not static (the balanced functioning of the asymmetrical brain, being, of course, another): they involve the harmony of opposing tendencies. A tightrope walker balances by making and responding to myriad tiny movements in the rope: completely stabilise the rope and the performer falls off. (Equally let it go too slack and the same happens.) The right hemisphere view is more inclusive than that of the left: stability can be explained by dynamism alone, but dynamic processes cannot be explained by static ‘things’ alone.

One very important element in all life is, of course, evolution. Many problems arise from seeing evolution as effectively the replacement of one element (a species) by another: as a chain, not a flow. ‘Organisms do not, of course, evolve’, writes Dupré. ‘Evolution relates to the distribution of the properties of organisms over time.’⁷⁷ Evolution is a flow that seamlessly connects all life. What seem like species are just our way of reifying that flow (‘thingifying’ it) at any one moment in time. As geneticist Charles Birch put it, ‘nuts and bolts cannot evolve! They can only be rearranged.’⁷⁸

Life is not a rearrangement of already known nuts and bolts, but the constant creation of something radically *new*.

Once one understands that one is dealing with flow, natural selection can be seen for what it is: a *stabiliser, not an agent of change*. Indeed, and fairly obviously, natural selection is never the originator of change at the gene level; it acts only to stabilise an already existing change. By selecting the most adaptive phenotypes, the lineage is stabilised over longer periods of time.⁷⁹ Equally, as we shall shortly see, genes are not stable elements in the story, unchanging unless by blind accident: they are themselves constantly changing or being changed, in highly adaptive ways.

3. Non-linearity

A serious problem for adherents to the machine model is that, while they are obliged by the model to explain organisms from the bottom up only, the deeper they go the less of anything remotely machine-like can be found. The scarcely material entities that physicists have grappled with over the last hundred years offer little reassurance that, if only we go to a more basic level, we are going to find a mechanism. As the biologists try to account for mind in purely material terms, physicists have increasingly been inclined to account for matter by appealing to mind.

However, long before we get down to the quantum level, things show no signs of getting simpler: they remain stubbornly as complex and animate as we go down in scale.

Here I'd like to pick up the observation that no organism develops as the result of the execution of a sequence of predetermined steps. Each developmental 'step' is not simply computable from the immediately preceding one. In a classical mechanism, causation is linear and can be clearly outlined. However, in biological systems, causation tends to follow not straight lines, but spirals, involving recursive loops, and multiple causes leading to multiple effects across a network, with sometimes competing factors cross-regulating one another, reciprocally interacting, and in ways we do not understand taking information from the whole. All this makes the classic idea of a two-element, cause and effect sequence unhelpful. 'The standard two-event model', according to philosophers of science Rani Lill Anjum and Stephen Mumford, 'does not handle this complexity well,

offering us just more and more of the same discrete two-events causally related.’⁸⁰ A mechanism, in other words.

The geneticist Philip Gell, speaking about his area of research, considers that ‘the heart of the problem lies in the fact that we are dealing not with a chain of causation but with a network’, something like a spider’s web, in which a perturbation at any point of the web changes the tension of every fibre in it.⁸¹ Context is everything. Which means we cannot simply account for organisms from the bottom up, but must do so *at least as much from the top down*. Not to mention from the sides, as in a web. We might be accustomed to thinking of biological processes in the abstract, isolated artificially by our mode of attention. But each element in each process is likely to be involved in several other ‘causative chains’, more like an unimaginably complex piece of choreography, where members of one group pass in and through another, for a while belonging to both or neither – each process having its own apparent end. According to Nobel Prize-winning geneticist Sydney Brenner, development ‘is not a neat, sequential process ... It’s everything going on at the same time.’ And, he continues, in words that strike at the core of the reductionist enterprise, ‘there is hardly a shorter way of giving a rule for what goes on than just describing what there is.’⁸²

This puts me in mind of some words of Marcelo Gleiser, here speaking of the whole material world: ‘When it comes to physical reality, there are no final explanations but ever more efficient descriptions.’⁸³ Not understanding – not even, necessarily, explanation; but description.

Until recently it was assumed that signalling pathways in cells were linear sequences, beginning from a defined starting point and progressing by an orderly sequence of steps to a defined conclusion. Somehow it was overlooked that each of these theoretically abstractable sequences was in practice interlocked at different points with other dynamically evolving sequences. A team of molecular biologists from Brussels decided to plot the interactions between just four cascades, each consisting of only five steps. The result, as they put it, is a ‘horror graph’ (see Plate 13[a]):

With four cascades of five steps, the number of possible positive and negative interactions is 760. This does not take into account the multiplicity of different isoforms of proteins at the different levels of the cascades, the multiplicity of effects of each intermediate in each cascade, the stimulation by a cascade of the secretion of

extracellular signals, or feedback or feedforward controls within cascades. In fact, so many interactions are now described (everything does everything to everything) that it is difficult to reconcile this concept with the known specificity of action of signals in each cell.⁸⁴

‘Everything does everything to everything’: interlocking, reciprocal and interpenetrating processes on such a scale show chains of causation to provide limited insight into cell responses.

But that’s not all. It’s not just that steps are related in a more complicated fashion than the machine model leads us to assume. It’s that the idea of there being *steps at all* (even if useful when focussing on the minuscule and the time-sliced) is misleading when looking at the whole over a duration of time. This is an idea that I mentioned in an earlier chapter, and will return to at various points in this book. It might not seem at first sight that significant. I hope to show that it is a crucial insight into what is peculiar about the way we in the West now tend to view the world. It is the difference between a sequence – a concatenation, a chain – and a single, indivisible movement, a flow. Flow is a process: a chain is a series of things, that are static until one is given a push or a pull by the thing next to it. An organism is a flow, and is alive. A machine is a chain, and is dead.

Can one even talk about causation in a flow? There are certainly temporal regularities, but does the earlier part of a stream *cause* the latter, in any conventional sense? For that, the two parts would have to be distinct entities. Alan Watts describes someone who has never seen a cat, squinting through a crack in a fence, and seeing a cat’s head appear, followed moments later by its tail. The cat turns round and comes back: first the head appears, then the tail. Later he sees another such event, and another. Eventually he draws the conclusion that the event ‘head’ causes the event ‘tail’, which is its invariable effect.⁸⁵ Causation could be seen as an artefact – a useful one – of time-slicing, slicing the flow. (It might be objected that, while it is true that no one part of a waterfall or a tornado causes another, it is surely possible to say that each, as a whole – the waterfall and the tornado – has a cause, or, at any rate, causes. But that depends on seeing the world at large as a collection of things, not processes. For where does the precipitation of rainwater, the configuration of the land, the air pressure, the wind speed that would be said to be their causes begin and end? I appreciate

that one argument might be that that is precisely why we need to think in terms of ‘things’; and it’s no doubt one reason why we do. But my claim is not that ‘thing-thinking’ has no uses – just that thinking in that way imports a whole set of assumptions that are, to say the least, open to challenge; and makes it difficult or impossible to see elements of the picture that we would be wrong to ignore.)

Similarly molecules, whether in an organic system or not, are ‘a part of a continuum of relational interactions’, more like a flow than a chain.⁸⁶ Beyond this, we have known since the 1960s that the behaviour of proteins cannot be fully described using linear, classical mechanics; and more recent research even demonstrates quantum entanglement between particles in two wholly distinct (as we would normally think) organisms, widely separated in space. Behaviour at the cellular level requires a quantum mechanical account in order to be understood, even if Newtonian mechanics is for most practical purposes an adequate, if approximate, fit.⁸⁷

Incidentally, this seems like a good moment to gloss the unfortunate expression ‘quantum mechanics’. After all, I am arguing that the machine model is misleading: what’s achieved by substituting one kind of mechanics – ‘quantum’ – for another – ‘Newtonian’? David Bohm puts it well:

The entire universe must, on a very accurate level, be regarded as a single indivisible unit in which separate parts appear as idealisations permissible only on a classical level of accuracy of description. This means that the view of the world being analogous to a huge machine, the predominant view from the sixteenth to nineteenth centuries, is now shown to be only approximately correct. The underlying structure of matter, however, is not mechanical ... This means that the term ‘quantum mechanics’ is very much of a misnomer. It should, perhaps, be called ‘quantum nonmechanics’.⁸⁸

Or, perhaps even, ‘non-quantum non-mechanics.’ I will discuss the model of quantum mechanics, and the related and even more powerful model, quantum field theory, in Chapter 24. It turns out that not only the word ‘mechanics’, but the word ‘quantum’, while certainly having a meaning, needs significant qualification.

Finally, unlike organisms, machines, including computers, do not operate in *Gestalt* fashion: when they are engineered so as to give the appearance of doing so – eg, facial recognition software – they do so still via rules and procedures applied to measurements, depending on trawling blindly and laboriously through vast heaps of data, in a process that speaks not of intelligence but its opposite. The linearity of this approach can no more reach the curve of true intelligence than straight lines, however many they be, can describe the circumference of a circle, though they may give the illusion of doing so. According to microbiologist Brian Ford,

the essential processes of cognition, response and decision-making inherent in living cells transcend conventional modelling, and ... reveal a level of cellular intelligence that is unrecognized by science and is not amenable to computer analysis ... biological systems are non-linear systems that are not amenable to digital modelling. As [the physicist Alex] Hankey has reminded us,⁸⁹ many are founded on unfathomable complexity. ⁹⁰

4. Not one-way action – maybe not even interaction?

A further problem with a machine model is that it suggests a direction of action of one thing on another. I have just suggested that it is usually myriads of ‘things’ having an action on myriads of other things. But even that is wrong. In organisms there is never just action without both *interaction* and *mutual construction*. Cause and effect in organisms, if it can safely be applied, is never unidirectional, but reciprocal. When an organism interacts with its environment, both parties change; each influences the other. And not in some minor, incidental fashion, either. When DNA is ‘active’ (as Lewontin points out, it is largely inert), most of the work is done by the cell environment. This, crucially, includes *the provision of information*, which is conventionally thought of as the role of DNA. Both cell and genome depend on their mutual interaction. As Schrödinger put it: ‘physical action always is *inter*-action, it always is mutual.’⁹¹

Research over the last 80 years or more demonstrates that it is not true that genetic change is simply due to accidents or damage to the DNA. Organisms actively reconstruct their genomes in response to their

conditions.⁹² Shapiro points out that the genome is actively shaped by the cell, as conditions change, over three distinct time-scales: first during cell reproduction, involving the formation of nucleoprotein complexes; then during multicellular development, involving epigenetic formatting; and ultimately in evolutionary change, involving changes in DNA sequence structure:

one of the main adaptive features of DNA-based heredity is that DNA is a highly malleable storage medium, permitting rapid and major changes to complex organisms without disrupting their functional integrity.⁹³

This has interesting consequences that may surprise some readers. C.H. Waddington found that heat-shocking pupae of the fruit fly *Drosophila* in some cases led to abnormal patterns of veining on the wings of the adult fly. If one continued to breed such cases together, heat-shocking the offspring, a point was soon reached where not only virtually all flies were abnormal, but their offspring continued to be abnormal *even without heat-shocking*. The number of generations necessary for the abnormal patterning to become fixed in the population was only 14 – too few for this to be supposed a coincident chance novel mutation. The gene expression had, it seems, been altered directly, and quickly, by the environment.⁹⁴

It is a standing joke among mechanists that cutting off the tail of a mouse does not produce tailless mice. However, scientists have developed microsurgery techniques that can alter the pattern of cilia on the surface of *Paramecium aurelia* (a unicellular organism). They found in a series of striking experiments that these changes were transmitted permanently to their offspring through the normal processes of cell division.⁹⁵ Similar phenomena have been demonstrated in other ciliates.⁹⁶

‘Today’s biologists’, writes the physicist Evelyn Fox Keller,

recognise that however crucial the role of DNA in development and evolution is, it does not do anything by itself. It does not make a trait; it doesn’t even include a ‘program’ for development. Rather, it is more accurate to think of a cell’s DNA as a standing resource on which a cell can draw for survival and reproduction ... it is always

and necessarily embedded in an immensely complex and entangled system of interacting resources that collectively are what give rise to the development of traits.⁹⁷

Let us just pause there for a second. DNA is ‘a standing resource on which the cell can draw for survival and reproduction’. Hardly surprising, of course – unless you had been led to believe, somewhat improbably, that organisms were ‘robot vehicles blindly programmed to preserve the selfish molecules known as genes’.

Another instance of reciprocal rather than unidirectional action, writes Dupré, is that of an enzyme, often described as working like a lock and key, ‘fitting just-so into whatever it’s acting on. Yet increasingly it looks as if the two actually accommodate one another, less a key in a lock than a negotiation on the fly.’⁹⁸ As one research group put it, ‘in reality, the activated receptor looks less like a machine and more like a ... probability cloud of an almost infinite number of possible states, each of which may differ in its biological activity.’⁹⁹

On another level, all multicellular organisms are involved in mutual, symbiotic relationships of various kinds with a host of microorganisms.¹⁰⁰ And the organisms, similarly, with the environment. Indeed, it is a good question whether the distinction between organism and environment can ever be other than approximate. In 1966, the experimental psychologist James Gibson coined the term ‘affordances’, referring to the opportunities afforded by an environment to an organism. The important point is that an affordance is not a thing, but resides in the relationship between an organism and its environment: the affordance requires both.¹⁰¹ What provides an affordance to one animal clearly may not to another, and may cease to be an affordance even for that animal at another moment in time. In this sense, affordances are emergent phenomena: they are opportunities for action that arise from a relationship and thereby define the organism as an agent.¹⁰²

Microbiologist Kriti Sharma, in her fascinating book, *Interdependence*, writes that ‘the cell is not exactly reacting to an environment, but is reacting *with* an environment, as oxygen reacts *with* iron and where *both are transformed*.’¹⁰³ Niche construction is often thought of as what Dawkins refers to as the ‘extended phenotype’ of the organism, a one-way process,

encoded in its genes and expressed through the animal creating external structures; yet, according to Dupré, this is to overlook that, equally, ‘the altered niche affects the behaviour and ultimately drives the evolution of the organism’. As he comments: ‘The difference in these perspectives nicely illustrates the difference between a thing- and a process-centred ontology.’¹⁰⁴ But we might go further: Sharma’s formulation of interdependence is not just one of interaction, but of *mutual constitution*. Organisms and environments do not

co-construct one another *sequentially*, as when an organism digests food from the environment and excretes wastes into the environment, which in turn change the organism’s metabolism, and so forth. Such a view still separates organism from environment and makes one the causal agent, and then the other, and so forth, so that agency shuttles between the two. The ‘reactivity’ view suggests that organism and environment are transformed *simultaneously*, and at each moment ... Rather, they arise *new* in each instant ... Moreover, this ‘arising anew’ occurs *dependently*— that is, phenomena bring each other newly into being in each instant.¹⁰⁵

The orthodoxy is that DNA affects the fate of the cell, the cell affects the organism, and the organism the environment. This is the bottom-up view. At least as true is the top-down view: that the environment affects the organism, the organism accordingly restructures the cell, and the cell makes appropriate use of DNA in doing so. In a letter to Moritz Wagner, Darwin wrote, on 13 October 1876: ‘In my opinion the greatest error which I have committed, has been not allowing sufficient weight to the direct action of the environment, i.e., food, climate, &c, *independently of natural selection* ... When I wrote the ‘Origin’, and for some years afterwards, I could find little good evidence of the direct action of the environment; now there is a large body of evidence’.¹⁰⁶ As Fred Nijhout, Professor of Biology at Duke, makes clear: ‘When a gene product is needed, a signal from its environment, not an emergent property of the gene itself, activates expression of that gene.’¹⁰⁷

Sharma asks for a radical shift in the way we conceive of living systems. She suggests that not one, but two, steps are needed:

The first is a shift from considering things in isolation to considering things in interaction. This is an important and nontrivial move; it is also a relatively popular and intuitive concept ... [But] to get to a thoroughgoing view of interdependence, I argue that a second shift is required: one from considering things in interaction to considering things as *mutually constituted*, that is, viewing things as existing at all only due to their dependence on other things. This second shift is potentially more subtle and difficult than the first, because though the first requires considering the mutual relations and influences *between* things, it does not actually require a change in the many habits and assumptions that usually commit us to viewing *things* as fundamentally independent.¹⁰⁸

One after another, causes that we conceived of as giving rise to an effect are shown to be at least to some extent, and in some cases to an even greater extent, themselves caused by the very effect to which they were supposed to give rise. We are used to thinking of metabolic processes as regulated by a cellular clock, though metabolic cycles can not only operate independently from such a clock, but themselves influence the circadian rhythms of that 'clock'.¹⁰⁹ In general, according to one researcher, 'it seems that connections between the circadian clock and most (if not all) physiological processes are bidirectional.'¹¹⁰ It also seems that while some gene mutations clearly do cause cancer, the majority of mutations found in cancer are the consequences, rather than the causes, of disruption of intercellular communication.¹¹¹ (The situation is made still more complex by the fact that, depending on context, the *same gene* can either promote or suppress the formation and growth of a tumour.)¹¹²

The activity of individual genes reflects the choreography of chromosomes, which reflects the larger choreography of the nucleus, which reflects the choreography of the cell and organism as a whole with the environment. Who, then, is sculpting whom? How can we know the dancer from the dance?

5. The 'parts' are themselves changing

A machine is made of parts that do not typically alter with their context. A tappet, a widget or a gasket continues its existence effectively unaltered wherever it is put. In an organism, unlike a machine, the ‘parts’ are continually engaged in changing themselves, sometimes radically, depending on context. One of the most obvious examples is that each cell has precisely the same DNA, yet that same DNA results in dramatically different kinds of cells arising, and hence different kinds of tissue, depending on context. While we assume a mutated gene to explain a malignant trait, write Sui Huang and colleagues,

nobody will doubt that normal cells as distinct as a stem cell, a mature neuron, a blood cell or an epithelial cell all share the very same genome. No mutations are invoked to explain the vastly different phenotypes and their inheritance within a lineage. This opens the first fundamental question: *how can the same set of genetic instructions produce a variety of discrete, persistent (non-genetically inherited) cell phenotypes?*¹¹³

The same ‘parts’ respond to quite different environments to produce utterly different effects.

An apparently ubiquitous phenomenon called ‘developmental system drift’ ensures flexibility in what a gene specifies.¹¹⁴ The result is that the same ends are repeatedly reached by quite distinct genetic means.¹¹⁵ In two species of roundworm, for example, ‘similar sexual structures arise from marked differences in signalling pathways, differences involving both novel wiring and novel protein modifications.’¹¹⁶ Different species of insects achieve segmentation using different mechanisms involving different genes, but with little overt difference in the outcomes.¹¹⁷ Detailed mechanisms can, of course, be identified for these developmental processes, but that’s not the point: ‘their details seem less important than the higher-level morphological “attractors” that exert a kind of downward causation ... on their permissible variation, which is rather prolific.’¹¹⁸ Whole outcomes may determine how ‘parts’ behave in order to reach them, at least as much as any of the ‘parts’ determines an outcome. Thus many paths involving ‘wide-ranging differences in the number, order, and kind of molecular events’ may lead to the same reliable outcome, and considerable variations

in genetic makeup can result in the expression of an identical phenotype, or form. Conversely, as we saw, identical genetic makeup does not necessarily result in identical outcomes in morphology; much depends on the context.¹¹⁹

I have already referred to another instance, that there are far more proteins coded for by DNA than there are genes to make them: what those genes make depends on the context and what is required in it. We saw that epigenetic ‘dials’ can create 2,000 or more variations of proteins from the same gene blueprint.¹²⁰ That the same genes can take on a number of roles provides a form of ‘belt and braces’ provision, ensuring that processes necessary to survival are preserved.¹²¹

Similarly, some genes are widely conserved across species. Pax6, the gene playing the critical role in the development of an eye, occurs in almost identical form in a range of species, enabling the development of a fly’s eye, a frog’s eye or your eye: yet the types of eye, how they are structured, and how they function, are very widely different (see Plate 13[b]).

And it’s by no means just genes that are so malleable in their function. What *any* molecule does changes according to what is required by the context, and at many levels throughout the organism. The enzyme phosphoglucose isomerase is ‘best known for its role in the process that releases energy inside cells, for example – but when outside the cell, it can perform at least four distinct functions, such as promoting nerve growth.’¹²² Similarly with neurotransmitters: for example, serotonin (5-hydroxytryptamine, or 5-HT for short), like other neurotransmitters, has remarkably diverse effects. It is widely known for its effects on mood, which partly explain the action of many antidepressants. But it also has many other uses: in cell division, blood clotting, bone metabolism, breast-milk production, liver regeneration, bowel function, appetite regulation, and sexual function – depending on the context.

Enzymes are notorious for their shape-shifting qualities, but proteins more generally are not the static structures they are popularly conceived to be, but continually cycle through different conformations.¹²³ Their structures and functions vary among cell types and change over the course of evolution. We now know that probably 30–50% of all proteins, the majority of which are not even enzymes, are so-called ‘intrinsically disordered’ proteins, lacking a fixed structure, and able to shift shape in a virtually unlimited field of possibilities (note the loaded language, which

speaks of the left hemisphere preference for stasis and fixity: not 'maximally flexible', but 'intrinsically disordered').¹²⁴

Since structure and function are inseparable, it is not just the molecule's function that changes, but its very structure. So it is with DNA. Genes are not things, not 'batons' to be handed on in the relay race of life. There is no such thing as Dawkins's ruthlessly selfish gene, determined to pass on its lineage unscathed, in the process dominating and exploiting that poor, blind robotic vehicle, the organism, to which it belongs. 'As genomes evolve, new genes are born and older genes may adopt novel functions, fuse, or disappear altogether,' writes systems biologist Adrian Verster.¹²⁵ Genes are malleable processes, subservient to the needs of the organism in which they happen for the time being to inhere.¹²⁶

This can be seen at two levels: changes in conformation, which affect gene expression of the same 'line of code'; and changes in the 'line of code' itself.

An example of the former is that something as simple as the degree of licking and grooming of her pups by a mother rat leads to changes in gene conformation, and therefore expression, in her offspring.¹²⁷ An example of the latter is the single-celled organism *Oxytrichia trifallax*, which gets rid of over 90% of its somatic genome, and re-organises the rest.¹²⁸ This is certainly an extreme case, but, according to philosopher of science Denis Walsh,

not an especially exotic one. The engineering of the genome by the organism is commonplace. Cells actively cut, transpose, copy and fix their genomes. They do so in highly sensitive, *adaptive* ways.¹²⁹

What that means is that *cells use DNA* to adapt to new ends; it is not a matter of *DNA using cells* to further its own 'selfish' ones. The idea that genes are somehow (how?) 'programmed' to pass on their DNA does not sit well with the fact that cells are constantly acting on it to change it or to repair it; and such persistence as there is depends on 'elaborate editing and correcting processes in the cell'.¹³⁰ These include anything from point mutations to large-scale genome rearrangements and whole genome duplications.¹³¹ There are 'massive levels of genomic rearrangement during development'.¹³²

It should not surprise us that the ‘parts’ of an organism change themselves, consume energy and turn over rapidly even though the whole structure persists, since life is *at every level* a dynamic process.¹³³ ‘Logically, the elements of a process can be only elementary processes, and not elementary particles or any other static units’, wrote biologist Paul Weiss.¹³⁴ One cannot explain a changing process by unchanging elements, though our extraordinary bias towards ‘thingness’, rather than forms or processes, encourages us to think that we could.

Sometimes biologists, says Dupré, talk as though they believe that organisms are put together

from bits of Lego ... Rather, living things are processes that are capable of assuming many protean forms: dynamic, ever-changing, but balancing, for a time, on just the right side of chaos.¹³⁵

‘Just the right side of chaos’: they are, in other words, what Naseem Nicholas Taleb calls ‘antifragile’ systems.¹³⁶ Taleb makes a distinction between robustness, which relies on resistance to change, but is susceptible to catastrophe when it finally can resist no more; and antifragility, which thrives on flexibility, makes small adjustments and thereby not only survives but *evolves*. All evolutionary processes are in this sense antifragile, constantly adapting, and because of their ability to permit constant small ‘errors’ (as they seem at the time) able to preserve themselves against final destruction. The expression ‘the right side of chaos’ reminds us that a system that is capable of flexible and rapid response to a multitude of possible occurrences must have inbuilt *instability*, as well as stability: the classic case of this is the Eurofighter Typhoon jet, a supremely agile fighter plane, which was built deliberately unstable so as to make it highly responsive. Because of this it can make swift and abrupt changes in direction that a more stable plane could accomplish only over many miles.

An organism must be capable of a vast repertoire of available responses, and some of them, unbelievably enough, are invented by organisms ‘on the hoof’, as we shall shortly see. Stuart Kaufmann writes that

genomic systems lie in the ordered regime near the phase transition to chaos. Were such systems deeply into the frozen ordered regime,

they would be too rigid to coordinate the complex sequence of genetic activities necessary for development. Were they too far into the gaseous chaotic regime, they would not be orderly enough. Networks in the regime near the edge of chaos – this compromise between order and surprise – appear best able to coordinate complex activities and best able to evolve as well.¹³⁷

Ultimately, even what we conceive to be the ‘solid’ parts of cells are actually flows. The living cell is mainly fluid, principally water. Even surfaces, cell membranes, the cytoskeleton, and the various fibre systems, that look relatively solid, are ‘subject to more or less continuous dissolution and reconstitution.’¹³⁸ We imagine the organism contains fixed structures because of the nature of left hemispheric attention, which replaces flow with frozen slices removed from time: our static diagrams, or photomicrographs.

6. The influence of the whole

While a machine has clearly defined parts, this is not, then, the case in an organism.¹³⁹ A process arguably has no parts and is, in reality, an indivisible unity. As Scott Turner puts it, ‘integrity and seamlessness seem to be the essence of an organism’.¹⁴⁰ To the extent that one can speak of an organism as having ‘parts’ at all, we find them by dismantling the whole in an inevitably somewhat arbitrary fashion. They are ultimately a product of human attention, a function of the way we choose to attend to the organism for a particular end of our own, and the parts we choose to define change depending on our focus of interest at the time.

Let us assume, however, for the sake of argument, that there are identifiable parts. These parts are unlike machine parts – and not just because they constantly change. For such parts do not, as those of a machine do, exist prior to the whole that they make up, but come about *at the same time* as the making of the whole. They are further examples of ‘mutual constitution’. They are not pre-existing entities put together, but instead distinguish themselves in the process of self-differentiation of a living whole: thus the liver, the heart, the kidneys are not assembled, but come into ever more defined being as the whole living organism grows.

And the relationships between the parts don't go to *make up* the whole, but *derive from* the existence of the whole. They are handy *post factum* mental representations. 'Parts' are inextricably involved with their context, without which they are both impotent and unpredictable; and neither the parts, nor even the local interactions of the parts on their own, account for the qualities of the whole organism that we observe.¹⁴¹

Lower levels of an organism are not straightforwardly explanatory of the higher levels. Microscopic findings do not predict macroscopic outcomes, nor vice versa. Walsh writes that 'as physical systems take on new configurations, they bring new phenomena into existence'.¹⁴² These phenomena are not easily accounted for in terms of phenomena at some more reduced level. Examples given by him include atomic nuclei, magnets, superconductors, excitable media, fluids and tissues, and organic agents.¹⁴³ As always, we are dealing with *Gestalten*, not with constructions.

In explaining a multicellular organism's stability, the intrinsic properties of what we see as the parts are of little significance compared with 'the dynamic relationships among parts at different levels of the organisational hierarchy.'¹⁴⁴ Note, dynamic relationships among parts *at different levels*. The existence of emergent properties at every level throughout the natural world suggests, too, that we are on the wrong track when we try to account for what we find in terms of things rather than processes. It would be like trying to account for the unique quality, the power and, yes, the *life* of a piece of music by examining each note, or at most a phrase, in ever greater detail, outside the flow of the whole work, in the hope that by this 'drilling down', as we say, there at last we will find the secret. We cannot account for a phenomenon at the topmost level merely by a concatenation of elements at the lowest level. We are dealing with a *Gestalt*. That is to say the 'betweenness' is more important than the 'things' we believe we discern within it. Relationships are prior to *relata*, a topic I will return to in Part III.

An aside on terminology. When I use the word 'betweenness', I refer, not just to what happens between two or more 'things', but to the unique whole in which we might later come to identify 'things' and the relationship between them. Thus an electrical current resides not in the negative pole or the positive pole, nor the space between the poles, but in the sum of all of these, *plus*, crucially, the wholly new element that comes about from 'adding them together' (which, of course, never happens except in our theoretical *post factum* reconstruction). There is no hitherto existing

adequate word for this idea in English, but the concept is important, so ‘betweenness’ will have to do. It is close to Sharma’s ‘interdependent mutual constitution’.

Molecular structures are good examples of entities that cannot be reduced to their parts: according to biochemist Ross Stein, ‘the essential nature of the compound subject transcends, and cannot be reduced to, the simples from which it is composed ... Complex objects are no mere aggregates, but possess a defining unity.’¹⁴⁵ And at the phenomenological level we see this all the time. As molecules form new wholes, utterly new qualities, unpredictable from the apparent constituent parts, emerge: so a tasty white crystalline substance – table salt – emerges from the compound of sodium, a dullish grey, malleable metal, and chlorine, an evil-smelling, poisonous, greenish-yellow gas.

Writing about the ways in which living systems display characteristics not to be found in their constituent parts, cell biologists Sophie Dumont and Manu Prakash observe that:

subtle variations in parameters (energy expenditure, architecture, and temporal dynamics) can dramatically change the mechanics of the resulting structure in ways we do not understand ... Emergent structures exhibit properties that their smaller building blocks (air molecules or sand grains) do not ... It is very likely the case that these mechanical design principles will be fundamentally new and as such may not have a known analogue in nonliving physical systems.¹⁴⁶

The expected conventional terminology of mechanics here seems awkward, and with good reason. For, if ‘mechanics’ are dramatically changed in ways we do not understand – and I have no doubt that they are – in what sense are they still mechanics? If the ‘mechanical design principles’ are ‘fundamentally new’, and have no ‘known analogue in non-living physical systems’, surely the comparison of organisms with machines (still implicit in the language with which, I quite understand, the researchers must write their paper if they wish to get it published) is self-confuting.

‘The astonishing plasticity of organisms contrasts with the brittleness of machines’, writes Nicholson,

which tend to stop working when their parts break or are damaged. Of course, redundancy and self-repair can be built into the design of machines to some extent, and although this can make their operation more robust and more reliable, the inherent limitations of their fixed architecture remain.¹⁴⁷

Here the question arises, how the part can have that sense of the whole to which it belongs, of which Barbara McClintock spoke. A machine as a whole typically does not adapt in response to parts becoming worn or defective, nor invent a solution at a local level that will further the purpose of the overall machine.

Carl Woese again:

Machines are stable and accurate because they are designed and built to be so. The stability of an organism lies in resilience, the homeostatic capacity to re-establish itself. While a machine is a mere collection of parts, some sort of ‘sense of the whole’ inheres in the organism, a quality that becomes particularly apparent in phenomena such as regeneration in amphibians and certain invertebrates and in the homeorhesis [see note] exhibited by developing embryos.¹⁴⁸

To quote Ford, ‘Although we now recognise that experiential input can bring about epigenetic modification of the cell nucleus, there must be undivined mechanisms that relate the experiences of the entire multicellular organism back to the cell.’¹⁴⁹ And even the single cell seems to have what the biochemist Jesper Hoffmeyer describes as ‘tacit knowledge’ that is ‘inherent within the cellular organization and must be presupposed by, rather than materially built into, the DNA description.’¹⁵⁰ Hence Shapiro’s claim that ‘life requires cognition at all levels’.

As yet, we have little idea of how the ‘parts’ seem to ‘know’ what whole they belong to, and how it should be shaped: it is an ancient question, to which no-one has ever given a satisfactory answer. One answer worth considering is that the part quite simply does not exist: the being can *only* be considered as a whole. As John Haldane noted:

From a consideration of the general characteristics which distinguish a living organism from a machine I had become convinced that a living organism cannot be correctly studied piece by piece separately as the parts of a machine can be studied, the working of the whole machine being deduced synthetically from the separate study of each of the parts. A living organism is constantly showing itself to be a self-maintaining whole, and each part must therefore always be *behaving as a part of such a self-maintaining whole*.¹⁵¹

The question, by the way, is not ‘by what immediate mechanism?’ – to be answered at the molecular level by speaking of, say, electrical gradients affecting the direction of diffusion of polarised molecules; an account which is at best a first step towards a description, hardly itself an explanation, let alone an understanding.¹⁵² That is like trying to understand a ballet by measuring the impact of ATP hydrolysis on myosin in the dancer’s skeletal muscle fibres. In the words of Ford,

Knowing how the intricate mechanisms within the cell perform tells us nothing of the entire cell, just as studying the hormone fluctuations and changes of blood pressure in a human subject would reveal little of why they were late for work in the first place ... It is as though we have clamoured for the most intimate insights into the minutest workings of the telephone exchange, while disregarding the subscribers – who they are, why they choose to speak, or what they are saying.¹⁵³

When they are injured, organisms – from simple bacteria, to trees, to complex vertebrates – are often able to heal themselves and repair the damage, regaining the form that was lost. Some organisms (eg, axolotls and salamanders) can regenerate entire body parts, including limbs, parts of the brain, and even the heart. Lobsters can regrow claws, spiders can regrow legs, and rabbits and certain species of mice can regenerate a number of their organs.¹⁵⁴ Although antler growth is peculiarly shielded from environmental influences, and although no two sets of antlers are the same, any one animal’s antlers are perfect mirror images of one another, and, if

both are cut off, will regain the same shape from memory.¹⁵⁵ Trees and plants, of course, have a multitude of individual and characteristic forms of their own, which are not principally moulded by the environment, and which they will strive to regain if their form is damaged (see Plates 13[c] & 13[d]).

Indeed, some relatively complex creatures, such as flatworms, can regenerate the entire body including their centralised brain, from a fragment of the original animal.¹⁵⁶ This was noted by Charles Darwin's grandfather Erasmus Darwin.¹⁵⁷ In one case a planarian, a type of flatworm, was cut into 279 pieces, each of which proved capable of generating a new body within a few weeks.¹⁵⁸ Each part appears to know what it lacks, and can thus regenerate a new whole. What is still more extraordinary is that if flatworms – the 'first' class of organism to have a centralised brain with true synaptic transmission,¹⁵⁹ and to share the majority of neurotransmitters that occur in vertebrate brains¹⁶⁰ – are decapitated, they not only regrow a head, but retain their memories; for example, which way to turn in a maze they had previously 'solved' before their heads were chopped off.¹⁶¹ A body is a moulded river indeed.

The preservation of form does not depend on trotting out 'pre-programmed' developmental blueprints.¹⁶² For example, the face of a tadpole is quite different from that of a frog; in order to produce the typical adult frog's face, a series of deformations must be carried out, and, along with it, various organs and tissues relocated. Surely, then, it follows the steps of a programme? Not in any obvious sense of the word. When developmental defects were artificially induced in a tadpole, subsequent development was able to adjust accordingly, apparently making corrections towards what it seemed to sense was its ultimate goal, the adult frog's face, despite there being no 'programme' or previously known mechanism to direct it.¹⁶³ Michael Levin, a prominent geneticist at Tufts, writes:

Most organs were still placed into the right final positions, using movements quite unlike the normal events of metamorphosis, showing that what is encoded is not a hardwired set of tissue movements but rather a flexible, dynamic program that is able to recognize deviations, perform appropriate actions to minimize those deviations, and stop rearranging at the right time.¹⁶⁴

The question is ‘where is the information?’ That is to say, the in-*form*-ation. Where is the overall *form* or shape of the being stored, as a whole, in service of which any mechanisms we can detect and measure would be acting?

We should remember that evolution, and indeed the reproduction of organisms, is not a flow of ‘information’ only in the abstract sense of that word – that of, eg, ‘information technology’. We should remember that information is not a *thing*: it is the capacity for a channel to create a new link between two processes. Evolution is a physical, embodied process, not reducible to pieces of data. Organisms flow down the ages by reproduction and by evolution, literally mingling bodies – their forms – at a moment in time and from generation to generation, something no machine does: every embodied reproduction is evolution in action, and every evolutionary advance is an embodied reproduction. Offspring of organisms, from single cell to *homo sapiens*, are not separately engineered from new material externally, but emerge as new whole forms from the material forms of the bodies of their parents. The flow is embodied and seamless.

Barbara McClintock discovered, in experiments conducted in the 1940s, and therefore before the structure of DNA had been determined, that the genome is not a static entity, but subject to rearrangement, and moreover that there were heritable changes in gene expression not caused by changes to DNA sequences: what we now call epigenetics. She reflected that a genome must repeatedly face ‘shocks’ of various kinds, for some of which it is prepared and to which it can respond in a ‘pre-programmed manner’. As she says, some sensing mechanism must be present in these instances to alert the cell to imminent danger, and to set in motion the orderly sequence of events that will mitigate this danger. That is in itself remarkable. But she saw something still more remarkable:

there are also responses of genomes to unanticipated challenges that are not so precisely programmed. The genome is unprepared for these shocks. Nevertheless, they are sensed, and the genome responds in a discernible but initially unforeseen manner ... in most known instances of such challenges the types of response are not predictable in advance of initial observations of them. ¹⁶⁵

These responses appear to be, as C.H. Waddington believed they were, due to information in the organism as a whole, not just localised to specific pre-existing, temporarily silenced, genetic mutations.¹⁶⁶ To quote Noble, ‘organisms seem to be very resourceful when challenged with knockouts, blockers or absence of nutrients. If we look for that ingenuity at the molecular level we may not find it.’ On McClintock’s discoveries, he comments:

She could not have anticipated the extent to which her idea would be confirmed by the sequencing of whole genomes ... [implying] the movement of whole functional domains. This is far from the idea of slow progressive accumulation of point mutations ... the rearrangement of whole domains including the functionality of those domains in response to stress could have been the origin of creativity in the evolutionary process ... This is why McClintock characterised the genome as a *highly sensitive organ of the cell*.¹⁶⁷

From all of this it would seem that an organism is not just driven from the bottom up. Decisions seem to be taken by the organism – even a single cell – as a whole; what’s more, intelligent decisions – ones that are creative and ‘hand-tailored’, not just selected from a predetermined repertoire – which in itself would require a (lower) level of intelligence. Considering a number of accounts of intelligence, Ford writes that common to the ‘different definitions of intelligence there is one concept on which all seem to focus: the ability to deal constructively with the unforeseen’:

The definitive demonstration of intelligence, must observe the cell encountering a situation which it cannot have previously experienced; it needs to demonstrate abnormal behaviour specifically in response; and the cell must act remedially to restore normality to its abnormal predicament.¹⁶⁸

Cells pass each of these tests with flying colours. And they do so, often, in an awe-inspiring balance between autonomy and co-operation that a human society might envy.

Everywhere we can observe this proclivity for ingenuity. When a surgical suture is secured with staples, the resulting repair is conspicuous and crude. Within weeks, the scar is healed, smooth, and scarcely visible. The cells at the site of the incision have identified the nature of the surgical trauma and have initiated manoeuvres to restore it. Capillaries re-form so that the microcirculation is restored, innervation is reinstated, and the many epidermal layers are properly reconstituted. None of this we understand. These complex processes are invisible to the brain, and are not controlled by cerebral activity, neither are they subject to regulatory intervention by circulating hormones. The cells are the decision-makers ... No computer model comes close to emulating the mechanisms manifested by an amoeba, as it seeks its way ahead, selects which food substances are suitable for ingestion, modifies its cell membrane to accommodate the situation and moves on in a direction it has motivationally selected. A team based at Sapporo, Japan, have even shown that amoebae have memory for events.¹⁶⁹ This takes us deeper into the realities of living cells than current conceptions of memory as the propensity only of cell aggregates. Single cells can take decisions; single cells can plan responses; single cells contain memory.¹⁷⁰

I will have more to say about all this in Chapter 25.

Another interesting example relates to the nervous system of animals, and concerns the well-known principle that ‘what fires together wires together’. Such plasticity (known as Hebbian, after Donald Hebb, the Canadian psychologist, who posited it) is widely considered to be the mechanism by which information can be coded and retained in neurones in the brain. ‘The general idea is an old one’, wrote Hebb, ‘that any two cells or systems of cells that are repeatedly active at the same time will tend to become “associated”, so that activity in one facilitates activity in the other.’¹⁷¹ With continued use, changes at the synaptic cleft mean that such neuronal sequences are preferred, and may even become semi-automatic, in a process known as kindling. This is well established, and is a process of positive feedback: more leads to more. So far, so good. Recently, however, we have become aware that Hebbian adaptations are just one of three possible changes that may occur with use. A second is the opposite. It is

homoeostatic: in other words, up-regulation causes a compensatory down-regulation – negative feedback: more leads to less. But even more interestingly, we now know there is a process called neurotransmitter switching, whereby the neurotransmitter involved at the synapse is swapped for another:

Significantly, transmitter switching often reverses the sign of the synapse: an excitatory transmitter is replaced by an inhibitory one or vice versa. These reversals in synaptic sign change the function of the circuits in which they occur, complicating the interpretation of the connectome ... ‘Neurons that fire together, wire together’ encapsulates Hebbian plasticity. ‘Neurons with chronic firing, reverse wiring’ summarizes the impact of transmitter switching.¹⁷²

‘Complicating the interpretation of the connectome’ looks like an understatement. Not for the first time we are brought to ask, what is causality? Certainly we cannot just close our eyes to what we are seeing and hold to conventional bottom-up (ie, from parts to whole) causation only, as the machine model suggests. (A bottom-up approach starts, in any case, only from what is *presumed* to be ‘the bottom’.) In organisms the whole is also necessary for the functioning of the parts: the part is apparently able to access information about the whole, and act on it in service of the whole. We may not know how, but that is not grounds for denying that it happens. One solution might be to accept that there are no parts as such, and that what we see is simply the action of a whole, as a whole: the problem lies in our perception.

If a cell is placed in a slightly acid medium, its mitochondria break up into small spherical beads. But, amazingly, on return of the cell to a normal medium, they merge again into strings, and eventually take on once more the appearance and internal structure of normal mitochondria.¹⁷³ Further, let us suppose you cut a developing limb bud out of an amphibian embryo, shake the cells loose from each other, and then allow them to aggregate once more into a random lump. You then replace the random lump in the embryo. What happens? A normal leg develops. The form of the limb as a whole dictates, according to Lewontin, the rearrangement of the cells:

Unlike a machine whose totality is created by the juxtaposition of bits and pieces with different functions and properties, the bits and pieces of a developing organism seem to come into existence as a consequence of their spatial position at critical moments in the embryo's development. Such an object is less like a machine than it is like a language whose elements ... take unique meaning from their context.¹⁷⁴

Or like a dynamic *field*. 'If the organism was simply its substance we would not be able to recognise it from one day to another', wrote Lawrence Edwards, an expert in plant morphology. 'Yet its being and largely its form are invariant from one moment to another, and from one day to another. The *form* can live within the flux. Something greater than the substance takes it up, moulds it, uses it, and then casts it away.'¹⁷⁵

Again, unlike in a machine, no two limb buds in a developing embryo are ever exactly the same; the buds of formative, mesenchymal cells develop each in their own way. The result is in each case a normal, fully formed limb of the kind dictated by its position. But not just its 'predestined' position: the same cell group in a limb bud can *nonetheless*, though destined to form the pattern of, say, a right limb, give rise to the mirror image, a left limb, with the opposite symmetry, simply by being transplanted to the opposite side of the embryo.¹⁷⁶

Another example of the whole somehow overruling the parts comes from fascinating experiments on the fruit fly, *Drosophila*. The absence of a gene, homologous to Pax6 (see above), causes the fly to develop without eyes. However, if such flies are interbred, they have been found soon to develop eyes – despite not having the gene in question.¹⁷⁷ Indeed, after 'knocking out' (disabling) both copies of a gene that had a normally important role in the development of a mouse, molecular biologists found that in many cases the mouse seemed unimpaired, and functioned normally.¹⁷⁸ In certain strains of mice, mutations in the *Kit* gene cause white patches on the tail and feet; if a mouse has one normal *Kit* gene and one mutated one, it will have the patches. Yet some of the offspring of such mice, who inherit two normal *Kit* genes, still have the white tail.¹⁷⁹ Resistance to viral infection in a nematode worm was achieved by some of the population having DNA that produced a viral-silencing RNA sequence;

when cross-bred with worms who lacked this DNA, some of the offspring inherited the antiviral mechanism and some didn't. All as one might expect. However, subsequent generations inherited the antiviral mechanism even if they lacked the required DNA. This non-DNA inheritance was followed successfully for 100 generations.¹⁸⁰ Similarly 'adaptive mutation' dictates that if a strain of bacteria is unable to utilise lactose, and is placed in a lactose-rich medium, 20% of its cells will quickly mutate into a form that enables them to process lactose: the mutation is then inherited by subsequent generations.¹⁸¹

Organisms don't just passively wait, then, for a lucky accident or resign themselves to dying out, but actively remodel themselves in response to changes in their environment.

As mentioned, changes in DNA are no longer thought to be mere accidents.¹⁸² Indeed Darwin himself wrote:

I have hitherto sometimes spoken as if the variations ... were due to chance. This, of course is a wholly incorrect expression ... Some authors believe it to be as much the function of the reproductive system to produce individual differences, or slight deviations of structure, as to make the child like its parents.¹⁸³

Another idea that perhaps does not square too well with the idea of genes bent on preserving themselves at all costs.

Everything depends on an organism's capacity to be flexible and responsive to its environment, just as the environment, both living and non-living, is responsive to organisms. It is this combination of interlocking responses that ensures stability. 'There is now good experimental evidence', write Jablonka and Lamb, 'as well as theoretical reasons, for thinking that the generation of mutations and other types of genetic variation is not a totally unregulated process.'¹⁸⁴ A seminal paper asserts that 'not all genome changes occur at random and that cells possess specific mechanisms to *optimize their genome* in response to the environment'¹⁸⁵ – not even the gene actively optimising the cell, but the cell actively optimising its genes. In a now famous paper in *Nature* it was claimed that 'cells may have ways of choosing which mutations occur', and they can 'learn from experience'.¹⁸⁶ Another has shown that 'bacteria that have lost their flagella

through deletion of the relevant DNA sequence can evolve the regulatory networks required to restore flagella and so restore motility in response to a stressful environment within just four days'.¹⁸⁷

In Shapiro's phrase, cells and organisms have evolved to become, 'cognitive (sentient) entities that act and interact purposefully to ensure survival, growth and proliferation'.¹⁸⁸ Evolution itself is an 'intelligent' process (he describes it as not only 'cognitive' and 'sentient', but 'thoughtful'). According to him, a twenty-first-century view of evolution implies

a shift from thinking about gradual selection of localized random changes to sudden genome structuring by sensory network-influenced cell systems ... It replaces the 'invisible hands' of geological time and natural selection with cognitive networks and cellular functions of self-modification. The emphasis is systemic rather than atomistic, and information-based rather than stochastic [random].¹⁸⁹

This is not only plausible, but no form of 'heresy'. According to Denis Noble, Darwin 'was concerned that he did not know the origin of variation and he acknowledged the existence of other mechanisms, including the inheritance of acquired characteristics.'¹⁹⁰ In *The Origin of Species*, he had written:

I placed in a most conspicuous position – namely, at the close of the Introduction – the following words: 'I am convinced that natural selection has been the main but not the exclusive means of modification.' This has been of no avail. Great is the power of steady misrepresentation; but the history of science shows that fortunately this power does not long endure.¹⁹¹

On the last point, however, he was sadly mistaken.

Cell biologist Bruce Lipton writes of the immune system, producing antibodies, that it

employs an amazing mechanism called *affinity maturation*, that enables the cell to perfectly adjust the final shape of its antibody protein. Activated immune cells make hundreds of copies of the original antibody gene. However, each new version of the gene is slightly mutated so that it will encode a slightly different shaped antibody protein. The cell selects the variant gene that makes the best fitting antibody.¹⁹²

This is further sculpted (by a mechanism known as somatic hypermutation) to become the perfect physical complement of the virus that it is to neutralise. What's more, the cell remembers this antibody shape and passes on the memory to its daughter cells.

In the late nineteenth century, Hans Driesch separated the two cells produced by the first division of a fertilised sea urchin egg and observed that each of these, which would normally have produced half of an organism, actually produced a complete *Pluteus* larva, the initial free-living form of the species. Each of these larvae was half the size of the normal *Pluteus*, but was complete in every detail and grew into perfectly normal adults.¹⁹³ 'How', asks Brian Goodwin, 'is the system organised so that when these two cells remain part of one embryo each produces half the future organism, but when they are separated, each produces a whole?'¹⁹⁴ Interestingly, Driesch compared the phenomenon with the bar magnet, which if divided produces two magnets, each with two poles.

One way of looking at multicellular organisms, including, of course, ourselves, is that we are historically an aggregate of single cell organisms that gave up their autonomy and co-operated, so as better to survive: we are ancient societies. Signals released by cells into the environment allowed for the co-ordination of a dispersed population of unicellular organisms. This enhanced the survival of single cells by providing them with the opportunity to live as a primitive 'community'.¹⁹⁵ Even the individual cell is itself the result of collaboration of many parts, including elements such as mitochondria which were originally bacteria that took up residence in the intracellular environment. The trillions of cells that go to compose our bodies, like the millions of people who live in a large city, share common purposes served by the adoption of widely different roles. And so do the trillions of commensal organisms – bacteria, mainly, on which our bodies

depend for healthy functioning. Until recently, bacteria were largely viewed as opportunistic inhabitants of the comfortable environment offered by the gut, but they are now known not just to be vital for digestion, but for the nervous system, the immune system and even for normal development at all.¹⁹⁶ They belong to the wider conception of ourselves as organisms: ‘commensal’ means sitting at a shared table: we couldn’t dine without their company. What counts as an individual – not just a part – depends on the question being asked, and the focus of our interest.

As has often been pointed out, bees, ants and termites behave like parts of a whole so tightly organised that they seem to act as if parts of one large organism. ‘A single termite is unintelligible’, writes Brian Henning,

apart from the collective organism of which it is a member ... as a single superorganism, the termite colony is extended in space and time, without clearly defined boundaries or a skin to define where the environment stops and the superorganism begins ... a single termite is no more an individual than a single cell in a petri dish solution.’¹⁹⁷

7. Imprecise boundaries

That leads to the next issue. A machine has clear boundaries; a natural system does not. The machine model involves being able to identify viably distinct, stable things as parts, and a viably distinct, stable thing – the machine – as the product of their combination. Processes, by contrast, can overlap in a way that ‘things’ typically do not. Processes ‘have boundaries that are fuzzy or indeterminate’, write Dupré and Nicholson:

Processes are individuated not so much by where they are as by what they do ... At no level in the biological hierarchy do we find entities with hard boundaries and a fixed repertoire of properties. Instead, both organisms and their parts are exquisitely regulated conglomerates of nested streams of matter and energy.¹⁹⁸

They liken organisms to Jupiter's Red Spot, which, 'by means of its continuous activity ... demarcates itself from the flux of its surroundings'.¹⁹⁹ Organisms are not tightly defined entities: neither even, as we saw, are some kinds of genes.²⁰⁰ The genome itself is not as defined as we imagine: 'it is not even clear that there is any unique entity that qualifies as the genome of an organism.'²⁰¹

Whitehead pointed out the artificiality of drawing boundaries to organisms:

The truth is that the brain is continuous with the body, and the body is continuous with the rest of the natural world. Human experience is an act of self-origination including the whole of nature, limited to the *perspective* of a focal region.²⁰²

We have seen that the environment is, in a concrete fashion, partially constituted by, and constitutive of, interdependent organisms, in which each is involved in the evolution of the other. 'Some of these interactions', according to Dupré, 'are so intimate and so fundamental to the survival of the organism that it has been hotly debated whether the interacting entities are distinct at all, or should rather be understood as constituting a single life.'²⁰³ The philosopher of science Argyris Arnellos writes that 'collaboration is one of the main characteristics of life and its evolution ... it is very hard to imagine life (both at the intra- and the inter-cellular level) that is not collaborative.'²⁰⁴

What he means by this can be illuminated by biochemist and philosopher Stephan Guttinger, who writes that 'symbiotic life forms are the rule rather than the exception in the biological realm':²⁰⁵

the significance of symbiosis examples in general is the realisation that the entities we used to refer to as single living things ... turn out to be less autonomous than we might have thought them to be ... it is not just the termite that shapes the mound and that has the power to digest, reproduce and survive, but a *system* of interconnected entities that has to be treated as the centre and/or origin of these capacities or powers.²⁰⁶

Too narrow a focus means that we conventionally think of organisms as sharply delineated individual entities, with linear causative relations. If, instead, we conceived them as systems, in which causation is both distributed and reciprocal, and these systems themselves nested in other, larger systems, and so on upwards and outwards, we would see a quite different picture unfold. We would then see, not just competition – that we would still, of course, see – but a combination of competition with *co-operation*. Such a relationship, in which division and union are fruitfully balanced, is what we mean by collaboration.

A superannuated myth of pop science has it that human beings evolved to be fundamentally selfish, striving to maximise their inclusive fitness by aggression and nepotism. As the anthropologist Christopher Hallpike reminds us, ‘studies of actual human behaviour, especially that of children show that, whatever evolutionary theory may say, while we must obviously act for our own preservation and well-being, we also have highly developed capacities for sympathy, co-operation, and group loyalty’.²⁰⁷

Ultimately we have common ancestors. As I suggested, evolution becomes problematic when species are thought of as one sharply defined thing replacing another. However, ‘this is no problem at all for a process. No-one expects a thunderstorm or a battle to have precisely delineated boundaries.’²⁰⁸ Living organisms integrate their cellular communities by mingling their bodies and sharing their genes. In this way they can acquire learnt experiences from other organisms.²⁰⁹ The boundaries of species are, in reality, blurred. In the words of Daniel Drell, Programme Manager of the US Government’s Joint Genome Institute: ‘We can no longer comfortably say what is a species any more’.²¹⁰

8. Boot-strapping

In the case of a machine, the instructions for making the machine cannot themselves be the product of the very machine they are designed to make. Even in a computer, the software is separate from the hardware: the hardware has to be finished, before the software can be extrinsically inserted into it. The code for making the machine is not being *simultaneously* written by the machine *in the very process of beginning to form itself as a computer*. By contrast, as philosophers of science Paul

Griffiths and Karola Stotz put it, with reference to the work of Susan Oyama,

the developmental information expressed in the organism is not present in the starting point of development, but is itself created by the process of development, through feedback from the current state of the organism to the states of the resources that will influence future development.^{[211](#)}

Even if computers can be brought to a point where they make apparently autonomous decisions, they can do so only because the capacity for them to do so depends on previous acts of human intelligence and human will. The ‘parts’ of an organism that are claimed to account for emerging phenomena lack adequate explanatory power, since the way in which those parts act when and where they do, and even their continued existence, cannot be understood without invoking the process they are supposed to explain, and, in something of an infinite regress, the processes to which, in turn, that process leads. A machine’s functioning is linear, whereas the process of living things is of entities that mutually co-arise.

WHY HAS THE MACHINE MODEL PROVED SO ATTRACTIVE?

In the face of such overwhelming evidence of the inadequacy of the machine model to the study of living organisms, why, then, does this product of the mid-Victorian mindset persist?

One reason is its simplicity. We are familiar with machines, and because they are what we are used to making, taking apart and putting together, it is perhaps a natural assumption that other systems, ones that we didn't make, will work in a similar way. This is particularly the source of the appeal in *molecular* biology, a discipline that necessarily concerns itself primarily with events that appear highly circumscribed in both space and time. Here chains of cause and effect tend to be abstracted from their wider context, and therefore seem to function in a broadly mechanical fashion. Molecular biology places 'the entire explanatory burden on a relatively stable, epistemically tractable entity: a one-dimensional digital code that can be replicated, modified, and transplanted from one individual to another'.²¹²

Regular and reliable patterns of behaviour discoverable in an organism are unreflectively assumed to demonstrate mechanisms. But regularities do not always mean there is a mechanism; nor do they imply determinism. Random events can cause predictable outcomes. The rain that falls at a random moment in time in a random distribution on a landscape encounters potential stored in the landscape; that potential is actualised in the predictable flow of water down to a river mouth into the sea. Similarly, accidental deaths are by definition unplanned. Yet roughly the same number of accidental deaths, around 17,000, occurs in the UK every year. There is not an emergency team of bungee jumpers on standby to make sure the statistics remain steady. It cannot be overemphasised that regularities in nature do not imply mechanisms, nor do they imply determinism.

Christopher Hallpike makes the point that convergent patterns of social evolution do not imply determinism. 'It is rather like the game of Monopoly', he writes:

the players are all different and the throws of the dice produce a completely different game each time, yet the underlying constraints

produce essentially the same result – a single player who owns everything and has driven all the others into bankruptcy. This is a good illustration that unique events, even randomness, and free will, are quite compatible with broadly predictable outcomes.²¹³

This is true without reference to the quantum nature of reality. But when one takes that into account, the case is strengthened. ‘Quantum physics showed that even the causal mode of description is only one very special way of tying together natural phenomena, and thus lawfulness in nature is not equivalent to mechanical causality’, wrote Bohr’s assistant Aage Petersen. ‘We have had to learn that the causal mode of description is a limiting case that encompasses only the simplest features of nature.’²¹⁴ Physicist David Oliver puts it like this:

Nature is neither inevitably random nor completely lawful and predictable ... Think of the universe as fabric woven on a loom. The warp threads are the laws of motion – rigid, and invariant, the weft, the emergent random strands that weave within the ordered warp. Together order and randomness form a creative whole ... There exist physical events the randomness of which cannot be dispelled by the most determined efforts to expose ‘a deterministic cause’ ... a stream of unpredictable information constantly enters the stream of definite information, a source of novelty, creativity, vitality...²¹⁵

Living things superficially exhibit some of the reliability and stability we associate with clockwork, though nothing about them in any way resembles clockwork, and they are, by many orders of magnitude, both much *less* stable, and at the same time much *more* reliable, than any machine.

I imagine some readers are thinking that, for all it may be a fiction, the machine model has persisted precisely because it has proved a very useful one. That is true enough. But that it can often prove useful does not mean it is true. In daily life, and even for most engineering purposes, we find it practical to assume that the earth is flat. If, however, we want not just to build a new garage, but to navigate the seas, the flat earth model is going to prove a serious handicap. In a conversation at the Niels Bohr Institute,

David Bohm was asked if ‘science has shown us something that scientists do not want to see?’ He replied:

Well, they have become so used to their way of seeing it, that they don’t want to change, you see they feel uncomfortable about changing. And they feel there’s no reason to change, they say we’re doing so well now, why should we change. In one sense it looks as if we’re doing very well, but if you look at the broader view, it looks very dangerous.²¹⁶

The purpose of science is not utility: it can never be reduced to ‘how can I most effectively exploit the world?’ Schrödinger was right: science’s aim is nobler than that. It is to understand nothing less than who we are. So the truth matters, and matters greatly. Furthermore, in the context of evaluating science as a path to truth – the purpose of this section of the book – it is, of course, the central issue. And the machine model is found wanting. As von Bertalanffy put it, ‘even as a fiction the machine idea does not attain its goal, because ... it proves to be inadequate in the face of a large and important section of biological data.’²¹⁷

It’s not even as though the fiction of the machine is harmless. It can be seen behind many of the more inhuman consequences of our technological society: our attitudes to both what human life is and to the living world at large. So, again: why does the model persist?

Probably not *just* because of familiarity or utility. The drive behind the machine model is, fascinatingly, much stronger and much less cold-blooded than an explanation on either ground would suggest. The sheer fanaticism of its advocates, and the *animus* directed at those who question the machine model, suggests a more impassioned investment, having little to do with science at its best.²¹⁸ I am inclined to think that one element in the model’s popularity is that it encourages the sense that we can easily understand what life is and learn to control it – Faustian fantasies, in other words, of omniscience and omnipotence, that reductionists quite rightly dislike when they see them attributed to a God (I share their qualms).²¹⁹

Here the attentive reader will hear bells ringing from Part I. Breaking down an entity into its parts to see how it works and attempting to build it up again so as to manipulate and control it are familiar proclivities of the

left hemisphere. So too is the phenomenon of denial, refusing even to countenance that a living organism might not be a machine when the evidence stares us in the face. It is reminiscent of the exclusively left hemisphere-dependent subject in Deglin and Kinsbourne's experiments insisting that a porcupine is a monkey, because 'it says so on the card'. Suggestive of left hemisphere dependency, too, is the facetious dismissal when its account of reality is challenged, something we saw in the cases of patients with right hemisphere dysfunction in Part I; and ultimately so is the anger which is ultimately provoked. The left hemisphere insists on its own vision, thereby interrupting the process whereby that vision needs to be referred back to the right hemisphere, so as to be taken up into the whole, as just one part – a valuable one, without doubt – of an understanding in context. Metaphorically speaking, it is as though many biologists now reside in the left hemisphere's hall of mirrors, and not only cannot find the way out, but have stopped being aware there is a world outside to attain.

The left hemisphere's serial, analytic approach is better equipped to deal with a system that is closed, static, linear and predictable – like a machine; not one that is open, constantly flowing, becoming and changing, and ultimately complex and indeterminate – like life. In the left hemisphere's vision, things take priority over processes. It is good at understanding linear cause and effect, not so much reciprocal interaction, let alone a process of co-creation. It understands a whole as simply the assemblage of parts, and causation as from bottom up only, not from many directions at once within the whole. It is at home when it can follow procedures; less so when it comes to recognising new forms, or fields, at work. It prefers what is clearly defined, to what has imprecise boundaries. It doesn't see *Gestalten*, of which life provides the pre-eminent examples.

This allegiance to the left hemisphere is, then, another reason why, however efficacious biology may have become in terms of manipulating the world, its claims to truth should be treated with care. But clearly a further question arises. If the hemisphere hypothesis, by positing the notion of left hemisphere capture, helps illuminate why biology has found itself in the strange predicament of claiming that black is white, why is it that physics, a science with the same pedigree of attachment to the machine model, should have escaped capture, as we saw in the last chapter that it had?

I think that the answer has much to do with the particular nature of Life. There are a number of aspects to this.

The reader will remember from Part I the difficulty the left hemisphere has with dealing with living things: its preference for inanimacy, its tendency to see parts of the body as lifeless ‘things’, its believing living beings (including the self) to be dead, its seeing people as machines or zombies, and its more general tendency to devitalisation. Then there is its tendency to halt the living flow of natural processes, substituting a succession of static representations, something I will say much more about in Part III. Encountering life, it needs to break it down into bits which can be manipulated and controlled; but life is ultimately recalcitrant to any such process. And, on top of all this, and most important, the left hemisphere can’t handle the concept of something with manifest intrinsic purpose (its own, inner, purposiveness), rather than something manifesting extrinsic purpose, engaged in instrumentalising or being instrumentalised by, its environment and other existing beings – the only kind of purpose the left hemisphere understands, and which is indeed its *raison d’être*.

In Part I, I quoted the philosopher Hans Jonas to the effect that the scientist assumes humans to be subject to causal laws from which the scientist himself is exempt. More than that, however, he saw that in this process inevitably ‘man-the-knower apprehends man-*qua*-lower-than-himself ... since all scientific theory is of things lower than man the knower’:

It is on that condition that they can be subjected to ‘theory’, hence to control, hence to use. Then man-lower-than-man explained by the human sciences – man reified – can by the instructions of these sciences be controlled (even ‘engineered’) and thus used.²²⁰

Philosopher of biology Stephen Talbott sent a draft book chapter to ‘a first-rank molecular biologist’; Talbott quotes from his response:

After describing my views as ‘very interesting, provocative, and necessary’, and before offering his support for much of what I had to say, he voiced this concern: ‘You very explicitly dispense with vitalism. Nevertheless, your piece is permeated by an atmosphere that says “There is something special about living things”.’

‘So I believe there is’, Talbott continues. ‘Animals and plants are a long way from rocks and clouds, and also from automobiles and computers. The need to point this out today is one of the startling aspects of the current scientific landscape.’²²¹

I agree with Talbott that, while there is no need for some ‘vital substance’ to be added for life to come about, there is obviously something special about living ‘things’. It borders on the absurd to deny it: and, as I have argued, organisms are just not machines. In a later chapter I will, however, argue that there is no absolutely hard and fast line to be drawn between the animate and what we call the inanimate. Not, of course, for the sort of reasons that usually lie behind such claims, those of the School of Nothing Buttery. Not, then, that the living is best seen by likening it to the inanimate; but, on the contrary, that the inanimate is best seen, as biophysicist Robert Rosen eloquently explained, as a limit case of the animate. That discussion will have to wait for now. What I want to draw attention to here is the curious phenomenon whereby scientists are made desperately uncomfortable by even the whisper of there being something special about living beings, or of their having intrinsic purposes of their own.

THE 'DREADFUL' QUESTION OF PURPOSE

The problem biology faces, but physics doesn't, is that the phenomena it is trying to explain require it to ask not one question, but two. This has been succinctly pointed out by George Gaylord Simpson:

'How?' is the typical, and only meaningful, question in the physical sciences. But biology can and must go on from there. Here, 'What for?' – *the dreadful teleological question – not only is legitimate but also must eventually be asked of every vital phenomenon ...* In biology, then, a second kind of explanation must be added to the first, or reductionist, explanation made in terms of physical, chemical, and mechanical principles. This second form of explanation, which can be called compositionist in contrast with reductionist, is in terms of the adaptive usefulness of structures and processes to the whole organism.²²²

Biology has a problem with teleology. In J.B.S. Haldane's oft-quoted words, 'teleology is like a mistress to a biologist; he cannot live without her but he's unwilling to be seen with her in public'.²²³ However, avoiding teleology results in vacuity, as the evolutionary biologist Ernst Mayr trenchantly observed:

Teleonomic statements have often been maligned as stultifying and obscurantist. This is simply not true. Actually, the nonteleological translation is invariably a meaningless platitude, while it is the teleonomic statement which leads to biologically interesting inquiries ...' ²²⁴

Mayr is thinking principally of those scientists – and they exist – who want us to avoid making specific teleological observations of behaviour, such as 'a turtle comes ashore *in order to* lay her eggs', by saying 'a turtle comes ashore *and* lays her eggs'. This seems like a hangover from the bad old days of behaviourism, where all inner life is denied, even in humans.

Yet, as Oxford professor of physics Andrew Steane says, ‘the structure of science is not one which dismisses the higher-level categories and “explains them away”. That is not what “scientific” means.’ Even Jacques Monod, an ardent reductionist, who is said (probably wrongly) to have said that ‘nature does not have any intention or goal’, wrote:

one of the fundamental characteristics common to all living beings without exception [is] that of being *objects endowed with a purpose or project*, which at the same time they show in their structure and execute through their performances ... Rather than reject this idea (as certain biologists have tried to do), it must be recognised as essential to the very definition of living beings.^{[225](#)}

Are we talking of the purpose of a single cell, or a single organism, or an evolutionary strain to which the organism belongs? All three: separating them out is to a large extent artificial, since they are different aspects of one process. At the macro level, according to palaeobiologist Simon Conway Morris, the development of the eye – improbably complex as it is – has happened independently 10 times (the camera eye six times and the compound eye four times) over the course of evolution.^{[226](#)} At an intermediate level, a strain of flies, genetically manipulated so as to prevent eye formation, within a few generations produces eyes. At the micro level, a single cell of the creature is capable of reacting to unforeseeable circumstances so as to preserve its function in the whole organism, in ways that suggest intelligence.

In a parallel situation, where the same mechanisms of echolocation in bats and whales were found to have evolved entirely separately, and depending in either case on the same complex co-occurring genetic changes, the first author, Dr Joe Parker of Queen Mary’s School of Biological and Chemical Sciences, London, commented: ‘We had expected to find identical changes in maybe a dozen or so genes but to see nearly 200 is incredible. We know natural selection is a potent driver of gene sequence evolution, but identifying so many examples where it produces nearly identical results in the genetic sequences of totally unrelated animals is astonishing.’^{[227](#)}

Importantly, the idea of teleology, or purpose, does not entail determination: no prior plan, involving a sequence of predetermined steps to bring it about, is required. It is exactly that that is avoided. For example, a young woman may purpose to be a mother, and this purpose may be the most important thing in her life, yet it does not entail a series of steps, nor can its path be predicted. Nonetheless, if it is important, it will tend to happen. A purpose here is not a plan. It is a *tendency* inseparable from – woven into, as it were, the fabric of – a life, which leaves all the detail, and even the final outcome, undetermined. Like ‘at-tending’, tending alters the world and makes it what it is for us. The root, in either case, is Latin *tendere*, to reach out to something – something, then, in front or above. Nothing to do with being pushed, mechanically, from behind or below.

The example can be usefully taken further. It would be easy to see how to *prevent* the purpose succeeding: for it to have a chance of succeeding, the woman must put herself in the way of its coming about. However, that leaves when, where, and with whom, completely undetermined and undeterminable. By doing or not doing certain things, the desired outcome can be made more likely. Both at the individual and universal level, purpose exists through what one might call a shaping of the probability landscape. Thus we tend towards certain ends, while leaving exactly what happens, and how, in any one case, undetermined.

To move from a focus on things as the ultimately important constituents of reality, to one in which processes are the important entities, requires a shift in our perception of space. We relinquish the idea of causation as strictly ‘bottom up’, from parts to wholes: we come to accept that whole systems contribute to the properties of their parts.²²⁸ The first is the only one that makes sense to the left hemisphere; in its view the whole can be understood only if we understand the parts. It takes the right hemisphere to understand that the parts can be understood only in the light of the whole.

But it also involves a shift in our perception of time. It is not just that chains of causation work from the past towards the future: the future, in the sense of internalised potential, pattern or *telos* – may be as important a driver in the emergence of phenomena as the past. As Joseph Woodger says, ‘in regard to the explanation, a knowledge of the *outcome* of a biological process is often more illuminating than knowledge of what went before.’²²⁹

Form in living creatures is, despite appearances, another aspect of the question about purpose: both imply a tendency, a direction of intent, an

overall attractive outline. Some ‘sense’ of this, as Woese and McClintock would say, is what enables the organism to repair, or correct, itself. In other words, to correct itself is an inclination towards a form that is its goal, towards a goal that is its form.

The purpose I am talking about is nothing extrinsic, but rather intrinsic potential that is fulfilled within a process as the process unfolds. ‘Latent within the polymeric sequence of amino acids that constitutes the enzyme’s primary structure’, writes Stein, ‘is directionality and potential for its correct folding into a catalyst of remarkable power and selectivity.’²³⁰ The forms that are required in the enzyme, in the cell, in the tree, may not be achieved by pushing from behind, but by drawing from in front, towards certain ends, certain conformations, certain attractors, much as a valley ‘draws’ water that falls evenly on the surrounding hills to one clear end: the mouth of just one river. There is stored attractive energy in the formation of the landscape.²³¹

So a system, including a cell or a multicellular organism, can be free and undetermined, yet despite the occurrence of random events, exhibit patterned and purposeful behaviour. To quote Paul Weiss:

Small molecules go in and out, macromolecules break down and are replaced, particles lose and gain macromolecular constituents, divide and merge, and all parts move at one time or another, unpredictably, so that it is safe to state that at no time in the history of a given cell, much less in comparable stages of different cells, will precisely the same constellation of parts ever recur . . . [yet] their joint behavior converges upon a nonrandom resultant, keeping the state of the population as a whole relatively invariant.²³²

Mutations have been supposed to be random with respect to fitness: those that bring benefit persist, those that do not die out. But such a claim requires clarity about how to judge fitness. This is far from straightforward. There is no clear way of determining fitness except in that a thing *does survive*, which is circular. The geneticist Theodosius Dobzhansky – the same man who said that ‘nothing in biology makes sense except in the light of evolution’ – wrote that no biologist ‘can judge reliably which “characters” are useful, neutral, or harmful in a given species’ (see note).²³³

Geneticist Henrik Kaessmann points to the recent discovery of protein-coding genes being composed *de novo* ('from scratch'), ie, from non-protein-coding genomic sequences altogether unrelated to pre-existing genes or transposable sequences. Such creation was widely thought to be virtually impossible: indeed, according to the famous French biologist François Jacob the probability for creation of new protein-coding genes *de novo* by random processes 'is practically zero'.²³⁴ And yet 'recent work has uncovered a number of new protein-coding genes that apparently arose from previously noncoding (and nonrepetitive) DNA sequences'.²³⁵ What is more, according to another research team, there is 'accumulating evidence that *de novo* evolution of genes from noncoding sequences could have an important role' in a class of genes representing 'up to *one third* of the genes in all genomes'.²³⁶

As Talbott points out, there has, until recently, been what looks like a doctrinaire assumption of randomness projected onto 'a descriptive biological literature that, from the molecular level on up, remains almost *nothing but* a documentation of the meaningfully organized, goal-directed stories of living creatures.' And he continues:

Here, then, is what the advocates of evolutionary mindlessness and meaninglessness would have us overlook. We must overlook, first of all, the fact that organisms are masterful participants in, and revisers of, their own genomes, taking a leading position in the most intricate, subtle, and intentional genomic 'dance' one could possibly imagine. And then we must overlook the way the organism responds intelligently, and in accord with its own purposes, to whatever it encounters in its environment, including the environment of its own body, and including what we may prefer to view as 'accidents'. Then, too, we are asked to ignore not only the living, reproducing creatures whose intensely *directed* lives provide the only basis we have ever known for the dynamic processes of evolution, but also all the meaning of the larger environment in which these creatures participate – an environment compounded of all the infinitely complex ecological interactions that play out in significant balances, imbalances, competition, cooperation, symbioses, and all the rest, yielding the marvellously varied and interwoven *living communities* we find in savannah and rainforest, desert and meadow, stream and

ocean, mountain and valley. And then, finally, we must be sure to pay no heed to the fact that the fitness, against which we have assumed our notion of randomness could be defined, is one of the most obscure, ill-formed concepts in all of science.²³⁷

In an earlier chapter I suggested that attempting to break down the *Gestalt* of the cat into a host of useful separate adaptations that enable it to hunt well, and then being faced with the question of what started the process and what led to what, creates its own problems. It is the linear, serial processing which the left hemisphere imposes on what is a complex whole. Similarly,

the evolution of complex adaptations requires coordination between an organism's various developmental systems. For example, the adaptive evolution of tetrapod limb structures requires coordination between the development of bone, muscle, nervous, circulatory, and integumentary systems (at least). If each system had to wait for a fortuitous mutation in order to produce the appropriate accommodation, complex evolutionary adaptations might never arise.²³⁸

There are aspects of the evolutionary process, as Scott Turner puts it, that 'make little sense without intentionality of some form guiding them'.²³⁹

To return to purposive behaviour in an individual organism. According to Ford, 'our conviction that these phenomena become manifest only through cell communities is a fundamental misconception. Ingenious, perceptive and intelligent behaviour is apparent in a single living cell.'²⁴⁰ No-one who has ever done such a homely thing as look at drops of pond water under a microscope would ever fall for the idea that purposive, intelligent behaviour is not exhibited at the level of a single cell. 'Single cells truly can consider their options', writes Ford, 'and modify their responses in the light of contingency':

Under the microscope, we can observe a predatory single-celled ciliated microorganism as it inspect its prey from a distance. The

ciliate can then select a specific microbial cell, pause, and then swoop upon its prey and capture it within a second. The coordination of this activity is similar to watching a cat catch a sparrow on the lawn, yet it is done within the confines of a single cell. Living cells are smart: the ciliate *Spirostomum* has been shown to possess memory.²⁴¹ It can be trained.²⁴²

Describing how cells often act apparently as individuals, so as to ‘seek out and destroy an invading pathogen without external mediation’, if necessary altering conventional behaviour to pursue it, and ‘maintain pursuit relentlessly until the organism is consumed and eliminated’, Ford reminds us that the human polymorph, a white blood cell that forms an important part of the body’s immune defences,

is an amoeba, although a constituent part of our bodies. This is a cell with a mind of its own. Conceptualising the human body as a cooperative community of essentially autonomous entities gives us a more reasonable understanding than our modern models, which see the body as a collection of mechanical organs enclosed in skin.²⁴³

Such behaviour, ‘including the continual and carefully choreographed machinations of mitochondria, the endless migration of granules and voiding of vacuoles, the conduction of discrete particles in two-way streams of cytoplasm like traffic on a highway, the meticulous changes of position of the nucleus in diatoms during division, and the cautious inspection of prey by a predatory ciliate’,²⁴⁴ leads us to see something inexpressibly more complex than we can explain, never mind understand. ‘Our failure to appreciate the majesty of the cell is astonishing, and our sublime confidence that we are close to an understanding [of] it is an embarrassment’.²⁴⁵

Slime moulds are amoeba-like organisms found on moist decaying organic matter. Clearly they have no neurones, each consisting of just a single, giant cell. They are, however, capable of behaviour that looks intelligent. They are attracted to one another and fuse, creating a plasmodium, which may be up to several metres long – the slime mould that is visible to human eyes. This plasmodium is essentially a flat, liquid-filled sac, but it behaves like an organised colony:

Every part rhythmically expands and contracts, pushing around the fluid inside. If one part of the plasmodium touches something attractive, like food, it pulses more quickly and widens. If another part meets something repulsive, like light, it pulses more slowly and shrinks. By adding up all of these effects, the plasmodium flows in the best possible direction without a single conscious thought. It is the ultimate in crowdsourcing.²⁴⁶

These plasmodia can make decisions, comparing different options (for example, food sources) and selecting the best one: the plasmodium touches all the potential meals and then either ‘decides’ to move towards one, or splits itself among many. It can even balance its diet.²⁴⁷ A mould can forage while making decisions with more than one objective, and it can be persuaded experimentally, as can humans, to behave irrationally at times.²⁴⁸ It even turns out that moulds make better decisions if they are not rushed.²⁴⁹

Plasmodia regularly break out of Petri dishes in laboratories, and can escape from traps and solve mazes.²⁵⁰ Slime mould colonies can learn to avoid certain paths that lead to a noxious stimulus, and moulds that have so learnt can transfer this memory of the adaptive response by cell fusion to new colonies that have never encountered the noxious stimulus. Even in cases where three out of four moulds in the fused organism were ‘naïve’ and had had no opportunity to learn, the information was transferred to the resulting fused slime mould from the one that had had the noxious encounter.²⁵¹

Does a slime mould have awareness? If it does, and I suspect it does, the awareness cannot be much like ours. It does have memories and would seem to act intentionally upon them. According to Scott Turner, ‘arguably, the roots of our own intentionality permeate deeply through the living world: the living world may be rife with intentionality.’²⁵² I believe this to be a reasonable deduction, and will have more to say about it in Chapter 27.

It seems to me that an explanation in terms of a whole that follows attractive formal patterns or fields – *Gestalten* – is better than an explanation in terms of chains of causation of parts. That we cannot as yet ‘see’ or measure such patterns or fields should not be a definitive argument against entertaining the possibility of their presence. Many physical forces

cannot be directly visualised or measured: we posit their existence only on the basis of their apparent effects.

Such is the case with a magnetic field. We visualise it through its effects on metallic bodies. Below is a simple illustration from D'Arcy Thompson, showing cytokinesis (a phase of cell reproduction) in a fish egg. The similarity to iron filings in the magnetic field of a bar magnet is so striking that it has been remarked on for 150 years.²⁵³

Fig. 28. 'Caryokinetic figure in a dividing cell (or blastomere) of a trout's egg. After Prenant, from a preparation by Prof Bouin.' (from Thompson 1992, 299)

ATTEMPTS TO SAVE THE MACHINE MODEL IN BIOLOGY

Allowing in the notion of purpose may seem ‘dreadful’ to most orthodox biologists clinging to the machine model, but of course that model itself does not dispense with the issue of purpose: it merely tries to brush it under the carpet. Every machine we know of is designed by an intelligent mind that is external to the machine, conceives the design before building it, and creates it for his own utility, a purpose that is extrinsic to the machine itself. Even a machine that makes another machine does so only because an intelligent mind that is external to both machines programmed, and purposed, the first to make the second. The machine is an embodiment in the external world of human will (whose residence is largely the left hemisphere) to some purpose, and the trail of causation inevitably returns, ultimately, to that source.

Clearly, if organisms are seen as mechanisms, there is a problem here. Because machines do not make themselves. Obviously one machine can make another, but no machine simply makes itself. Saying that this one ‘just does’ – La Mettrie’s ‘clock that winds itself’²⁵⁴ – is to say that it is, blatantly, not helpful to compare it to a machine. As Nicholson says,

the trouble with design-talk in biology is that, as we have already discussed, organisms are not extrinsically purposive objects ... The very idea of ‘design without a designer’ is not only deceptive – it is also logically contradictory: ‘design’ means made by a designer.²⁵⁵

On the one hand, biologists speaking the language of mechanics do not want to invoke a heavenly engineer (nor do I); but on the other, as I have already suggested, few biologists any longer believe that just waiting for the right sequence of accidents – random mutations – is how nature works.

One solution to this conundrum is genetic animism – Dawkins’s genes with an agenda. Externality and instrumentality are inescapable logical requirements in whatever it is that one claims drives the machine model. So for genes to do the necessary work to support the machine model, they must both carry the idea of instrumentality, and be in some way external to – ontologically, causally and temporally *prior* to – what they are making (the

rest of the organism). But this gambit ‘promotes the misunderstanding that DNA stands in contradistinction to the rest of the components in a cell by virtue of its ability to exert executive power over cellular operations’.²⁵⁶ We have seen that this falls down on every count. DNA is not ontologically, causally or temporally prior to the cell, nor does it stand over against the cell in any sense, bring it into being for a purpose, or simply exert power over it.

The other possible gambit to save the machine model is really just to reinvent God, put his eyes out, and call him by another name.²⁵⁷ The analogy of the world to a watch, which implied the existence somewhere of a watchmaker, was used by the English clergyman William Paley to buttress his argument for a God. Dawkins, the author of *The Blind Watchmaker*, used the same analogy to buttress his argument against God. He writes that ‘I suppose people like me might be labelled neo-Paleyists, or perhaps “transformed Paleyists”’.²⁵⁸ However, this does not help, for two substantial reasons: organisms are not at all like a watch; and evolution ‘simply does not proceed like a watchmaker, blind or otherwise’, as Nicholson points out.²⁵⁹ Both Dawkins and Paley make the same mistake, as Dawkins himself hints.

It has been argued that there might be a way out: that there is no need of a watchmaker, blind or otherwise, since complex structures can arise ‘naturally’ without a will that already conceives what it is that is being built. They ‘just do’. Fair enough: as I say, I am not arguing for an external mechanic, either. But, although the statement may well be true, it is in itself no form of explanation. It merely states as a fact the very thing that was required to be explained and remains to be explained. It simply kicks the can down the road. This would not matter (after all, no sane person thinks they can ‘explain’ the workings of life or the universe), if it were not offered in the spirit of having settled something at last.

The principle relied on in such accounts is that of self-organisation. As to what exactly self-organisation means, let me quote an authoritative source:

To express as clearly as possible what we mean by self-organisation in the context of pattern formation in biological systems, we provide the following definition: *self-organisation is a process in which pattern at the global level of a system emerges solely from numerous*

*interactions among the lower-level components of the system. Moreover, the rules specifying interactions among the system's components are executed using only local information, without reference to the global pattern.*²⁶⁰

On the basis of what we have considered so far, never mind what we are to consider later in the book, this looks like a deeply problematic claim. Since it is impossible to rule anything out definitively, I will not say 'impossible', but, all things fairly considered, 'improbable'. It seems merely an expression of a dogma, that of reductionism.

Turner writes: 'To honestly deal with the question at hand here – where does design come from? – there is no way of avoiding the problem of intentionality: it is the 800-pound gorilla sitting in the corner.'²⁶¹ This is surely wrong: the gorilla is sitting, not in the corner, but in the middle of the room. 'The living world is not only a designed place', he concludes, 'it is, in its peculiar way, an *intentionally* designed place ... a living phenomenon replete with the purposefulness and intentionality that is the fundamental attribute of life itself.'²⁶² Let me say, before the howls begin, that neither he nor I are arguing for an engineering God. What we have to explain is how there is order, complexity, beauty and purpose, while at the same time accepting that what we are dealing with is not a machine, and it has no *extrinsic* purpose, such as a machine has – it does not fulfil, in what would have to be an instrumental fashion, the purposes of something external to it.

There's a good deal more to say on purpose and design, and it's something I will return to towards the end of the book (see Chapter 27).

In a last ditch attempt to save the machine model, it may be objected that some machines can, or could potentially, be so programmed as to simulate some of the behaviours of organisms. With the growth of expertise in artificial intelligence it might in theory become possible for machines to simulate some of the operations of an organism less approximately, although the sheer scale of complexity involved in simulating the growth, regulation and development of a single cell – or part of a cell – is so daunting that I wouldn't be inclined to hold my breath. 'A single neuron would be more than enough for us to tackle, and even that is probably not amenable to our primitive methodologies', wrote Ford in 2017:²⁶³

For centuries, we have been led to envision life as machinery. The simplistic belief that the brain is a computer, and can be analysed through electrochemical means, is no longer sustainable ... The unfathomable complexity of a living cell is not generally appreciated; even a simulation of the way a mitochondrion moves would be beyond our current conventions. Emulating fragments of our trivial understanding does not explain their intricacy, for cells are intelligent, and they live lives that we have hardly begun to address.²⁶⁴

Often mentioned in this context are servomechanisms, whereby feedback is employed to make a system self-regulating: like a thermostat, the machine incorporates elements that enable it to achieve an equilibrium. However, organisms are open, far-from equilibrium systems; and as Nicholson points out, ‘servomechanisms are closed, near-equilibrium systems and consequently they are not capable of truly adaptive self-maintenance.’²⁶⁵ Adaptive: remember McClintock’s unpredictable adaptations to unforeseen circumstances?

But suppose for the sake of argument that such machines could be made: what then? Once the machine model is so transformed that it is no longer in any recognisable sense mechanical, it has lost its point. If, in order to make humans appear like machines, you have to posit machines that appear like humans, the metaphor is no longer doing any work. Nicholson takes the example of a paper by Reginald Kapp entitled ‘Living and lifeless machines’, in which

Kapp notes that ‘the living body is analogous to a motor car in which the chassis, brakes, cylinders, pistons, connecting rods, valves and bearings all contained combustible material, some of which was burnt whenever the driver placed his foot on the accelerator’.²⁶⁶ The question we must ask is this: how is such a bizarre imaginary motor car still analogous to an actual motor car? ... what is the point of clinging on to the [machine concept of the organism] if the price to be paid is that our understanding of machines has to be completely distorted in order to accommodate the characteristic attributes of organisms?²⁶⁷

Kapp is by no means the only author to stretch the machine concept beyond breaking point. The history of biology is, according to Nicholson, 'littered with memorable examples'. The attempt is reminiscent of an old joke:

What's green, hangs on the wall and whistles?

I give up.

A kipper.

But a kipper isn't green!

Well, you could paint it green ...

And it doesn't hang on the wall!

Well, you could hang it on the wall, couldn't you?

Anyway, it certainly can't whistle!

Look, what do you expect – to have the answer handed you on a plate?

All attempts at stretching the machine model in one form or another come down to repeating de La Mettrie's absurdity, that of a 'clock that winds itself'.²⁶⁸ The correct conclusion to draw is not that some watchmaker, blind or otherwise, did or does wind the machine, but that it is not a machine.

THE STREAM OF LIFE – A BETTER MODEL?

The words for Nature in Chinese, *tzu-jan* (*ziran*), and in Japanese, *shizen*, mean whatever is ‘of itself’, exists ‘spontaneously’, is ‘just what it is’. They are, in origin, adverbs, not nouns – ways of being, not things.²⁶⁹ If there is anything in this ancient perception, and I believe there is great wisdom in it, a vision of the natural world as a thing, and a mechanical one at that, is bound to restrict our understanding of what we are dealing with to a certain rather alienating perspective. A machine implies existence of an external creating force with its own purpose: Nature delights in her own.

In the history of Western philosophy there is a distinction between nature considered as *natura naturans* (nature ‘naturing’) and as *natura naturata* (nature ‘natured’), a distinction which, in that form, probably goes back to the early thirteenth-century polymath and scholar Michael Scotus, but is derivable from Aristotle.²⁷⁰ Famously, it was later taken up by Spinoza and Coleridge. It is the distinction between an eternally becoming, never completed, self-creating Nature, on the one hand, and an already finished, passive Nature, created by a cause external to herself, on the other. The second of these, *natura naturata*, suggests reification (‘thingification’), and, I submit, the view of the left hemisphere; the first, *natura naturans*, suggests flow, and the view of the right hemisphere. (As Arran Gare points out, Friedrich von Schelling, a late eighteenth- and early nineteenth-century philosopher whom we will encounter repeatedly at key points on the path ahead, foresaw many of the developments that have taken place in the post-mechanical science of the twentieth century: his influence was acknowledged by the physicist Hermann Weyl;²⁷¹ he was the first to describe the central concept of homeostasis, as well as process biology and was an influence on Haldane and Waddington; and laid foundations for both complexity theory and evolutionary epistemology, as well as the idea of the Earth as a living organism, which we now think of as the Gaia hypothesis.)²⁷²

Our troubles in this area, as in so many others, begin with the tendency to start from *things*, as though they were the important underlying elements in what we are looking at. Physicists have come to realise that the phenomena they are dealing with, though they may have some thing-like

properties when viewed from a certain perspective, are better seen as processes. The ‘building blocks’ of the supposedly mechanical universe behave like patterned flows of energy, or force fields: they are constantly moving and changing, have no precise boundaries, overlap and mingle with other equally elusive entities, cannot be precisely predicted or specified, change their nature and behaviour depending on circumstances and context, including whether or not they are observed, and exhibit behaviour that defies any mechanical principles – for instance, a ‘particle’ showing interdependency, or entanglement, with another too far removed across the universe for information of any kind to have had time to travel between them. Matter, it seems, is just, as Einstein confirmed, a particular manifestation of energy; not static and substance-like, but constantly in a state of flow.

Thingness places the emphasis on distinctness and stability; the problem then is to explain how things come to change, to move, to be connected, to overlap with other things, to change their nature when observed, or when the context changes. On the other hand, thinking in terms of patterned flow places the emphasis on interconnectedness and change; the problem then is to explain how apparently distinct entities arise for a while, and how it is they contrive to remain temporarily stable.

John Haldane went so far as to say ‘the conception of a “thing”, or material unit, is ... useless in the interpretation of distinctively biological facts’.²⁷³ But his point applies not only to organisms, and it is not just confined to descriptions at any one particular scale. Science always deals with processes, everywhere, and at all scales. That is its nature, and it is why science is such a wonderfully living business. ‘Classical science emphasized order and stability’, wrote the chemist and Nobel Laureate Ilya Prigogine. ‘Now in contrast, we see fluctuations, instability, multiple choices, and limited predictability at all levels of observation.’²⁷⁴

The most static of sciences might appear to be geology; yet its subject matter is, as philosopher Peter Simons points out, eruptions, earthquakes, the formation and erosion of rock and soil, the movement of tectonic plates, the dynamics of precipitation, the formation of rivers and much else. Astronomy deals with the explosion of supernovae, bursts of gamma radiation, the formation and decay of stars and planetary systems, and the rotation of galaxies.²⁷⁵

In chemistry, too, the fundamental entities are processes. According to Ross Stein, the molecule endures through time, maintaining its identity, like a macro-system, ‘not because it is static and unchanging, but rather because it is a dynamic system’: molecules are ‘dynamic entities that negotiate complex energy landscapes.’²⁷⁶ In physics, nothing rests even for a moment: electromagnetic radiation is emitted, propagated and absorbed; there are constant fluctuations in field values.²⁷⁷ As philosopher of science Mark Bickhard writes:

the best contemporary physics demonstrates that there are no particles at all. The fundamental constituents of the world, according to quantum field theory, are dynamic quantum fields in a dynamic space-time. Quantum fields manifest *particle-like* properties in virtue of their interactions being constrained to occur in multiples of fixed quanta, and the conservations of those quantised properties. The quantisation is *reminiscent* of particles, but it is in fact a quantisation of wave-like processes, not particles ... *there are no physical particles* ...²⁷⁸

Dupré and Nicholson take the argument further by positing that particles are the product of a way of attending:

Quantum fields, which are dynamic organizations of energy distributed in space-time, appear to have purged classical notions of elementary particles from the ontological picture ... Although contemporary physicists still routinely speak of ‘particles’, these no longer refer to solid micro-entities or tiny impenetrable granules, but to quantised excitations of particular fields. Quantum fields, in other words, are primary, and the various kinds of particles that physicists refer to are derivative entities, appearing only after quantisation.²⁷⁹

Niels Bohr thought it would be a step forward to eliminate the term ‘particle’ altogether.²⁸⁰ It was too much like a thing. Thus what were formerly considered the primary ‘building blocks’ of matter have been replaced by ‘statistical patterns, or stability waves, in a sea of background activity.’²⁸¹ And in the early 1950s von Bertalanffy, in a beautiful and

succinct formulation, made an explicit analogy between physics and biology:

As in modern physics there is no matter in the sense of rigid and inert particles, but rather atoms are node-points of a wave dynamic, so in biology there is no rigid organic form as a bearer of the processes of life; rather there is a flow of processes, manifesting itself in apparently persistent forms.²⁸²

It seems to me that the reason that the world looks different at the very small scale from how it looks at the level of the everyday has as much to do with time as it does with space. When we are looking at the molecular, and much more at the subatomic, level, processes are happening very fast indeed compared to the period of human observation. At the macroscopic level processes are generally slower. And this makes a crucial difference to what we seem to see. To quote John Dupré again:

Mechanistic explanations will be successful only to the extent that the constituents identified are sufficiently stable on the timescale of the phenomenon under investigation ... their success should not be taken as a sufficient reason for inferring that the organism really is an interlocking system of mechanisms. It is not.²⁸³

From where I am sitting I see the mountains of Skye, and Uist over the water. If a time-lapse camera had been set up to record this scene from the origins of the world to the earth's eventual destruction, we would see these emblems of enduring facticity rise quickly like waves and then, more slowly, fall away into nothingness.²⁸⁴ The most solid-looking manmade objects in the world, say the pyramids of Giza, are quicker, smaller waves – but waves they are. They look static only because relative to our period of possible observation they are flowing slowly. And so it is with everything. Whether something is considered static or flowing is only a matter of scale.

Both in time *and* in space. If we stand on the mountains, instead of looking at them afar off, we see that, at the level of the stone and earth and dust beneath our feet, the mountains are changing and flowing to some extent all the time; go on down to the level of the atom and beyond, and we

find that all is, once again, wholly a matter of flux. Stasis is just an illusion of observational scale, both spatial and temporal.

Scale – quantity – also changes quality in a broader way. This is something we seem inclined to forget: we often seem to believe that if something is good as it is, more of it must be better still. But quantity, always and everywhere, changes quality. And though this fact is nowhere more important than in the realm of human everyday experience, human society and human civilisation, it is also true of all systems. *Qualities* that obtain at the small scale disappear, and others come into being, emerging as the scale and the degree of complexity changes.

Importantly the left hemisphere and the right hemisphere have different takes on both space and time. It is something I will deal with at greater length in Part III. In brief, the narrow, piecemeal scope of the left hemisphere, together with its desire for precise targeting, aims to freeze its object, and hold it motionless in a slice of time; the broad, sustained scope of the right hemisphere, and its desire to see the whole, allows it to appreciate flow, what one might call the depth of time. Similarly the left hemisphere flattens space, so as to produce, once again, a slice, while the right hemisphere, seeing the whole of the world in the round, appreciates depth in space.

A single peripheral nerve acts as a seamless functional unit, every part contributing to the same goal. Yet if we take a slice across it, as if interrupting flow in time, it looks like this:

Fig. 29. Transverse section of a peripheral nerve

It seems to consist of a lot of separate units: how does it come about that they are they related? However, if viewed along its length, the nerve looks like this:

Fig. 30. Longitudinal section of a peripheral nerve

What were previously separate particles are now seen to be interlocking waves.

The ancient Chinese saw this problem, and expressed it as the way one looks at grain in bamboo: ‘on the straight it is of one kind, on the transverse it is of another kind. So the mind-heart possesses numerous principles.’^{[285](#)}

Fig. 31. Transverse structure of bamboo

Fig. 32. Longitudinal structure of bamboo

The best analogy is with music. Take this chord from the end of the *loure*, the sixth movement of Bach's French suite no 5 in G major:

This constellation of notes makes no sense at all on its own and is a howling discord: the notes A, B, C and D are sounded simultaneously. Try it, if you have a keyboard to hand. However, in the context of the flowing lines that harmonise together, it does not sound discordant, but takes its place in a pleasing resolution of lines designed to be heard together, and making sense only in relation to one another:

Once the left hemisphere has frozen its object in time, and decontextualised it in space, it is left with fixed, clear, distinct but inert parts, which then have to be reconnected and reanimated; the building

blocks have to be put together again, and the power, as it were, switched on. To the right hemisphere these ‘objects’ are already connected, animate, and in motion: the power was never switched off.

The left hemisphere’s take on change is that it must consist of the rapid succession of one static element by another. This may look like flow, but it is in fact its opposite: a concatenation – a chain of elements that are themselves static, and distinct – which do not merge one with another. There are always gaps, however infinitesimal, between the entities we imagine as things. This stasis and disconnexion is nowhere to be found in flow.

Discreteness and flow are both aspects of reality, but the latter is ontologically prior to the former. What quantum field theory has to say about this I will postpone to Chapter 24; for now I will content myself with quoting David Tong, Professor of Theoretical Physics at Cambridge:

At a fundamental level is nature discrete or continuous? I see no evidence whatever for discreteness. All the discreteness we see in the world is something which emerges from an underlying continuum ... Quanta are emergent ... they are not built into the heart of Nature.’^{[286](#)}

Analysis never stops until it reaches unchanging particles: if these parts took to changing (and they do), it would have to split them up in their turn.^{[287](#)} It can end only once separation and stasis have been achieved. The difference between flow and the rapid substitution of static elements may sound no big deal, especially since the invention of ciné film, and subsequent digitised media. But it changes a whole host of things.

Living beings cannot be understood simply by reducing them to an aggregation of parts. Knowledge of the parts can often bring useful information, but that is not the same thing. And in today’s science establishment what is most highly rewarded is seeing minutiae in the whole – the more minute the better – not the whole in which the minutiae inhere. Both exercises are important: according to Schrödinger, much more the latter.

Models are very powerful predictors of the path science will take, and the findings it will encounter. If it is true that each science progresses from

an initial conception of its relevant phenomena as *things* – substances such as phlogiston or vital fluid – to one in which they are seen as *processes*; and if it is true that, as Mark Bickhard asserts, process is now ‘the dominant language of science’, exceptions remain. What are they? Oddly, as he points out, ‘the sciences and philosophies of mind and persons. Here substance and structural views are still dominant.’²⁸⁸ This is just as David Bohm predicted.

Trying the stream of life model would be worth it, just to see what it revealed, even if it didn’t look like a much closer fit – as it seems to me it clearly does. The stream of life model is more capacious than, and is able to accommodate, the strengths of the machine model for what it is worth, where it helps: it maintains what Dupré calls ‘as much analytical sharpness as reality allows’, while giving full acknowledgment to fluidity and flexibility.²⁸⁹

But seeing life as a stream is also a model, just as the seventeenth-century Cartesian machine is. And a model is only truer than another if it explains more of the phenomena we see – or have *failed* to see, because of the tyranny of the formerly ruling model. The new model, too, can be jettisoned, when the time comes, once it has done its work. But to judge it fairly does require deploying it, and mentally inhabiting it for long enough to see what difference it makes to the observed world. In other words, you won’t even be in a position to see what it has to offer without first making a leap of imagination.²⁹⁰ Dismissing it just because it isn’t the model you now hold is senseless. In a well-known formulation, ‘you don’t see something until you have the right metaphor to perceive it’.²⁹¹

In 2004, Carl Woese, whose work revolutionised microbiology, wrote of the complacency he saw in biology at that point in history:

Look back a hundred years. Didn’t a similar sense of a science coming to completion pervade physics at the nineteenth century’s end – the big problems were all solved; from here on out it was just a matter of working out the details? *Déjà vu!* Biology today is no more fully understood in principle than physics was a century or so ago. In both cases the guiding vision has (or had) reached its end, and in both, a new, deeper, more invigorating representation of reality is (or was) called for. A society that permits biology to become an engineering discipline, that allows that science to slip

into the role of changing the living world without trying to understand it, is a danger to itself.²⁹²

And he concludes, in an image that should resonate in the mind of the reader: ‘molecular biology could read notes in the score, but it couldn’t hear the music’.²⁹³

Let us return to our overarching context, which is, after all, the examination of science’s claims on truth. I am a believer in Pragmatism. Science is Pragmatist, or should be; not merely pragmatic. The machine model may be useful at times, but it is not accurate, because, as I have tried to show, it does not answer to what we know of organisms from observation, examination, and experiment – in other words from science as she should be practised. This trade-off between truth and utility is also that between the dispositions of, respectively, the right (more truthful, but more complex) and left (less truthful, but simpler) hemispheres. Unfortunately, science’s claims on truth are compromised if they are hijacked by the left hemisphere refusal to acknowledge the limitations of its chosen model of re-presentation (here, the machine model). And, as I say, it is not as if this hijack has no consequences in the world of every day: the consequences are of the most serious nature.

How would a paradigm shift, such as the one I believe we need, change the way we thought of ourselves – influence, in other words, how we answered Plotinus’s question?

In the first place, it would help us, quite simply, to avoid viewing ourselves as machines, the most crippling possible distortion of what it means to be a human being. Believe it or not, in the Royal Institution Christmas Lectures for 2013 (‘the UK’s flagship science series’, according to its website, aimed at aspiring young scientists), an Oxford biology lecturer used the very specially human act of two people gazing at one another to impress on her indeed impressionable audience of 11–18 year olds that ‘you’re amazing, we’re all amazing, because we’re all hugely complicated *machines*...’²⁹⁴ Perhaps it had slipped her mind that machines are not social beings; that they don’t have consciousness, feelings, personality, will or individuality; that they have no appreciation of music, dance, poetry, art or nature; that they have no sense of humour and they do not have the ability to change their minds, to sorrow over the past or project a delighted future. And that’s not even taking into account the far more

complex issues entailed in human consciousness, including imagination, morality, creativity, the capacity for spiritual awe, and an allegiance to beauty, truth and goodness. And in case that should sound the slightest bit rarefied, I'd like to mention that they don't have bodies either. And they do not die. It is true, of course, that you're amazing, we're all amazing; but it's precisely because we are *not* just hugely complicated machines. If we carry on talking like this to the aspiring young, we will get no better scientists than we will deserve.

As biochemist Addy Pross writes, this dire process begins at the cellular level:

There is a growing awareness of an elephant in the room. Life is more complicated than a representation provided by a string of 3 billion letters. The gap between the elucidation of the human genome sequence and understanding the significance of that sequence is cavernous. The uncovering of more and more structural and mechanistic information within the living cell hasn't clarified what life actually is ... Our attempts to view biological systems as mechanical–materialistic machines have failed dismally.²⁹⁵

And those attempts are encouraged by the fact that scientific research into the human being, and specifically into the brain, is almost exclusively carried out using the model, and the language, of the machine. Neurospeak is replete with references to 'wiring', 'circuitry', 'modules', 'switches', 'signals', 'data banks', 'inputs', 'outputs', and to the brain 'encoding', 'computing', and having 'mechanisms' of every conceivable kind: and no-one knows better than I do from personal experience how hard such terms are to avoid, given the existence of the culture. Yet Berry is surely right to say that 'we should banish from our speech and writing any use of the word "machine" as an explanation or definition of anything that is not a machine. Our understanding of creatures and our use of them are not improved by calling them machines.' It is to be expected that the hermetic response of the left hemisphere will be that living creatures are machines. But we do not know that: we only see the mechanical aspects revealed by our model, and I hope in the course of this book to give the reader some insight into how limiting and damaging this habit has become. The language we use is

hugely important: it determines what we can understand. ‘Over the past fifty years or so’, wrote David Mermin in 1990,

scientists have allowed the conventions of expression available to them to become entirely too confining. The insistence on bland impersonality and the widespread indifference to anything like the display of a unique human author in scientific exposition, have not only transformed the reading of most scientific papers into an act of tedious drudgery, but have also deprived scientists of some powerful tools for enhancing their clarity in communicating matters of great complexity. Scientists wrote beautifully through the nineteenth century and into the early twentieth. But somewhere after that, coincident with the explosive growth of research, the art of writing science suffered a grave setback, and the stultifying convention descended that the best scientific prose should sound like a non-human author addressing a mechanical reader.²⁹⁶

Sadly, these words are yet truer today.

In the second place, we have been taught to regard ourselves as selfish, and the natural world out of which we emerge as essentially a field of ruthless competition. This has truth. But it is very much a half-truth. Its opposite is also true. We are moral beings, capable of selflessness, fulfilled through our interconnectedness with one another and the natural world at large. We are not atomistic. And the story of life on earth is not therefore one of competition only. It is at least as much, and arguably more, as I have already suggested, a story of co-operation and collaboration. In fact collaboration might be seen as, *sensu stricto*, ‘one of the central characteristics of life’.²⁹⁷

‘Complexity’, says Pross,

facilitates the replicative process ... in [a recent] experiment it was found that a single replicating RNA molecule was relatively ineffective at self-replication, but a pair of similar RNA molecules, neither self-replicating but each helping the other replicate, worked way better. Conceptually one can think of that step as the first on a thousand-mile journey toward that biological cell – a highly

complex cooperative entity, highly effective at making more of itself.²⁹⁸

Multicellular organisms appear to have arisen from single cells numerous times independently in the course of evolution.²⁹⁹ This alone implies that collaboration is a fundamental element in the evolution of life. According to Dupré and microbiologist colleague Maureen O'Malley, 'single animal or plant cells are only truly alive when they are collaborating with other cells ... in a great variety of ways.'³⁰⁰ Though it is part of our idea of living beings that they are autonomous entities, the very integrity of their function as a whole, on which such an idea of autonomy depends, *itself already* involves a host of other organisms.³⁰¹

This does not at all rule out competition: in fact the combination of competition and co-operation is just what collaboration means – and needs. As always, the forces for division must be balanced by those for union, and vice versa, though ultimately the two tendencies must be fruitfully unified, not divided. A collaborative team requires difference, not sameness, of types, strengths and roles; and every *society* – a form which life from its earliest origins approximates, even within the single cell – contains, and must contain in order to be healthy, elements of both difference and sameness. Communities of cells, according to Dupré and O'Malley,

exhibit well-defined cell organization and a functional division of labour that includes specialised cell-to-cell interactions, the suppression of cellular autonomy and competition, metabolic collaboration, combined defence and attack strategies, and the coordination of movement, growth and reproduction.³⁰²

And, as they go on to say,

whatever sense we might try to make of the Dawkinsian idea of selfish genes, molecular replication is always, and has always been from the pre-cellular molecular community to the present, the achievement of ensembles of molecules, not of individual molecules.³⁰³

And the entities that are seen to compete are already collaborations of ‘many different lineage-forming entities.’³⁰⁴

They see competition as a necessary stage in collaboration, ‘transitional’ rather than ‘terminal’:

temporarily competitive wholes will exhibit a strong tendency ultimately to compete most successfully by engaging in new levels of collaboration with similar or different entities ... our concept of collaboration assumes no sharp boundary between selfish and cooperative interactions, something surely to be expected *if the former is inclined to evolve into the latter*.³⁰⁵

I would also add here: on the whole, evolution has led to greater genuine collaboration, greater empathy, greater beauty and greater harmony. When reductionists want to demonstrate the brutality of nature, they are generally reduced – fittingly – to citing creatures such as the ichneumon wasp that lays its eggs in the larvae or pupae of another species, and the fascinating and, I agree troubling, lives of parasites (on which see Chapter 27). I don’t say that all is sweetness and light as we ascend the evolutionary tree, far from it: man, in particular, is a deeply flawed being – as well to remember that, when we pretend to be able to peer into the nature of the cosmos and find ready answers. But the very reason we are capable of deliberate harm is bound up with our special power to do deliberate good. (Social evolution, on the other hand, is another matter: I do not agree with Stephen Pinker that we are becoming better human beings. Though I fully understand his argument, I believe we are becoming less fully human, as we sacrifice what we could have learnt from attending to our right hemisphere’s understanding of the world.)

CONCLUSION

In the longer term many of our present assumptions about Nature, in both the broader and the more restricted sense of that term, may need to be revised, which is why at the largest possible scale it is still ultimately unpredictable: ‘Surprise is inherent in the structure of the world’, says Lee Smolin. ‘Nature can throw us surprises for which no amount of knowledge would have prepared us.’³⁰⁶ Jacob Bronowski once commented: ‘The physical scientists have more fun. Their theories are more eccentric; they live in a world in which the unexpected is everyday.’³⁰⁷ But *all* is unexpected if we could just see it. It’s just that physicists have learnt to expect the unexpected; many biologists are still in a preceding phase, in which the unexpected is dismissed, covered up, or simply not seen at all.

Things are changing, if slowly. Even one of the world’s most influential professors of mainstream bioengineering, Jay Keasling at Berkeley, together with three of his distinguished colleagues, wrote in a collaborative review published in the high-impact journal *Cell*:

An open question is whether biology is genuinely modular in an engineering sense or whether modularity is only a human construct that helps us understand biology ... In the context of biological engineering, it is still an open question whether abstraction is a useful tool or a necessary evil.³⁰⁸

It is both a useful tool, *and* it is an evil – how necessary depends on what you want science to do for you. Ultimately, it is not that the machine model does not have a role. There does not have to be just one model here. But, crucially, as in all hemispheric differences, one is more widely and fundamentally applicable than the other. Low-level analyses versus portrayal of the whole: it’s not an either-or matter, but if you want to *understand* the whole, it’s clear which is more important. Mechanism is a perfectly useful way of looking at tiny details in a complex picture so as to be in a position to manipulate them. There it has had spectacular successes. But we mustn’t be blinded by them. The problem is thinking that the same thinking will help you understand the whole: it can’t. ‘In its prime each

system is a triumphant success', wrote Whitehead: 'in its decay it is an obstructive nuisance. The transitions to new fruitfulness of understanding are achieved by recurrence to the utmost depths of intuition for the refreshment of imagination.'³⁰⁹ That is what we now need.

Haldane wryly noted of Pasteur that his work

appealed most strongly to those who desired to stress the contrast between mind and matter ... It is perhaps not quite irrelevant that he worked in his later years with half a brain. His right cerebral hemisphere had been extensively wrecked by the bursting of an artery when he was only forty-five years old; and the united brain power of the microbiologists who succeeded him has barely compensated for that accident.³¹⁰

Because *understanding* is more than providing a low-level description, the similarity to the understanding of a text is not accidental. To quote Lewontin again: 'An organism is less like a machine than it is like a language whose elements ... take unique meaning from their context'. Analyses of individual words and their possibilities of meaning can be an essential first step: without a knowledge of the words, we cannot grasp the whole. But at the same time, it is only the meaning of the whole that gives the individual words their full and proper significance. This, in a nutshell, is the truth that has for so long been ignored within biology.

As always, what the left hemisphere sees *must* serve the more inclusive vision of the right hemisphere, not come to dominate it. It makes an invaluable servant, but a tyrannical master. Failure to observe this principle leads to the neglect and obscuration of the most fundamental insights into the question posed by Plotinus, addressing which, according to Schrödinger, is the only justification for science: 'and we – who are we, anyway?'

INSTITUTIONAL SCIENCE AND TRUTH

Most human institutions, by the purely technical and professional manner in which they come to be administered, end by becoming obstacles to the very purposes which their founders had in view.

—William James ¹

Specialization is for insects.

—Robert Heinlein ²

SINCE SCIENCE, UNLIKE, SAY, REASON OR INTUITION, IS NOT JUST A FACULTY of mind, a way of approaching the world, but a vast edifice of human individuals working on projects, forging careers and shaping a culture, we need to look at the institution of science itself in order fully to assess science's claims on truth. For most people this is science's most evident manifestation, and one without the mediation of which they can have no knowledge of science, and therefore no access to whatever truth it may hold.

No-one these days is in a position to evaluate the validity of science's myriad pronouncements across more than the tiniest part of the whole range of what it treats. Even the most eminent scientist in his or her limited field, must rely, as we do, on authority, on the pronouncements of others. In fact every published paper is an instance of taking something on someone else's authority, on the understanding that peer review can vouch for its validity.

In answer to the all-important question at the core of this part of the book, ‘Where should we go for truth?’, the limitations imposed by the institution of science, are, whether we like it or not, almost as important as the limitations imposed by the nature of science itself. Whenever someone says ‘science teaches that ...’, they are relying, at best, on a broad knowledge of the published literature – most often not even that. Essentially, they are arguing from authority. So the question inevitably arises, how reliable is that authority?

The thrust of this chapter will be slightly different from the path we have been following, one which relates the hemisphere hypothesis to our approaches to truth. This chapter is necessary because science’s claims to truth cannot be assessed independently of an examination of the institutions of science; but I don’t wish to overstate the connexion with the hypothesis. There are indeed echoes, even resounding ones, and I shall point them out. But I think it is important that people should be aware of the degree to which the institution of science may fall short of the ideal in its pursuit of truth, without also having to be too concerned with the question of how much this can be attributed to the behaviour of our brain hemispheres. The phenomena are staring us in the face without the need of any hypothesis to illuminate them.

I imagine that most people who are not practising scientists have a view of how the institution of science operates that goes something like this. Research is carried out as a collective, collaborative enterprise in which everyone is disinterestedly doing his or her specialist bit in pursuit of the wider goal; bright young scientists are hired because they’re clever and original, then given their head, but supervised by wise professors who’ve been around, and whose broad grasp of the subject sensibly tempers their juniors’ lack of experience. Findings are published only after rigorous examination by peers, who act as objective arbiters of worth in their specialist area. Public science draws on such evidence in a balanced way to come up with policies promulgated to the population at large, based on a suitably extensive base of sound knowledge.

No doubt examples of such model scientific enterprise exist and we are all the beneficiaries of them. But the actual practice of science often falls far short of this and it is worth anatomising the various ways in which this happens, to the detriment of both science and truth, and of the public at large – that’s us all.

SPECIALISATION AND ITS IMPACT ON ORIGINAL THINKING

Science is the victim of its own extraordinary success. Such has been the exponential growth – the explosion – of scientific knowledge in the last three centuries, that all scientific enquiry has now to be highly specialist in nature. This means that many scientists are now so specialised that they often fail to understand the significance of anything outside their own narrow field, or how the work they do fits into the broader project of science as a whole, never mind into the field of philosophy and the humanities in general, and hence the lives of human beings – as Schrödinger saw that a scientist's work ultimately must, if it is to mean anything.

On this important matter it is worth quoting the historian and polymath Arnold Toynbee. He objected to what he called the importation of the 'bureaucratic state of mind', essentially the view of the left hemisphere, into the field of intellectual enquiry: he saw it as both out of place and obstructive, since 'in intellectual enquiry, freedom is the breath of life ... debate is the source of advances in knowledge and understanding, and ... the wider the field of discussion, the greater the chance of striking out fruitful new ideas.' He pleads for a demolition of the 'interdisciplinary dividing walls' to be replaced, in a striking image, by a structure

not like a Western house, but like a Japanese house, in which the internal arrangements can be given any number of alternative configurations, interchangeable at a moment's notice, because the interior is divided up by movable screens, not by walls that are 'permanent fixtures'.

He concludes, in an evocation of the necessary balance involved, that

This means that the panoramic and myopic approaches do not only benefit, both alike, by being made concurrently, but need each other's complementary services so much that no inquirer can afford to neglect either of them ... This, in turn, means that inquirers who

concentrate on the bird's-eye view and those who concentrate on the fly's-eye view are, not natural enemies but natural, and indeed indispensable, allies ...

Much as the right hemisphere understands the need for the left, but the left does not understand the need for the right, generalists appreciate the need for specialists, while the specialist is less able to see the need for the generalist. And Toynebee continues, later,

specialisation has become an indispensable intellectual tool. But being indispensable is not the same thing as being all-sufficient ... the farther that specialization is carried, the more of the meaning of the phenomena is left unplumbed in the unexplored gaps between the specialists' deep but narrowly constricted borings. This method leaves critical questions not only unanswered but unasked. And they will remain unasked if the microscopic approach is not supplemented by a panoramic one. Without a combination of the two, there can be no stereoscopic vision.³

This I believe goes to the nub of the matter: 'both/and', not 'either/or'. At present we have largely just one. We need to see with *both* eyes.

In an era where not just every organ, but every organelle, has its journal, and in which the jargon of each speciality becomes increasingly intimidating to outsiders, there is little incentive to look beyond the boundaries of your own ever narrower specialism. Indeed, the way to get on is to dig deeper in the hole you are already in, not to look around you to work out what all this spadework is about. For that way lies career death: you will cease to be an expert – one who has been defined as knowing more and more about less and less. As the physicist John Archibald Wheeler memorably observed, 'if you're working on something new, then you are necessarily an amateur.'⁴

Astronomer Jack Eddy reflected:

Entering a new field with a degree in another is not unlike Lewis and Clark walking into the camp of the Mandans. You are not one of them. They distrust you. Your degree means nothing and your name

is not recognized. You have to learn it all from scratch, earn their respect, and learn a lot on your own. But I also think that many of the most significant discoveries in science will be found not in but between the rigid boundaries of the disciplines: the terra incognita where much remains to be learned. It's not a place that's hidebound by practice and ritual. I have always tried to keep moving between fields of study...⁵

If perceiving shapes is how maths and science progress, as I believe it is, you will see those shapes only by rising above the hole where you are digging. The view in the valley floor is good, but if you never climb, you will not know that there are many other valleys, and mountain ranges nearby, which are not only beautiful in themselves, but help you see *why* good work needs to be done down in the valley floor at all. To quote Smolin, science gets reduced to technical problem-solving, and 'it is a fantasy to imagine that foundational problems can be solved by technical problem-solving within existing theories'.⁶

'General ideas, hypotheses, are necessary in science itself', wrote the philosopher John Dewey:

They serve an indispensable purpose. They open new points of view; they liberate us from the bondage of habit which is always closing in on us, restricting our vision both of what is and of what the actual may become. They direct operations that reveal new truths and new possibilities. They enable us to escape from the pressure of immediate circumstance and provincial boundaries. Knowledge falters when imagination clips its wings or fears to use them. Every great advance in science has issued from a new audacity of imagination.⁷

For those who would rather hear a scientist on science than a philosopher, here is the palaeontologist George Gaylord Simpson:

Science, truly to be such, must centre not on descriptions and names but on principles – that is, generalizations, theories, relationships, interconnections, explanations about and among the facts.⁸

Science can never be merely the extension of technique, as it often now seems to be. Knowing how to do something is not the same as understanding it; expanding know-how, our power to control, exponentially, without any concomitant advance in wisdom, is dangerous. It's like putting machine guns in the hands of toddlers. In 1991 Jonas Salk, who developed the polio vaccine, said: 'At one time we had wisdom, but little knowledge. Now we have a great deal of knowledge, but do we have enough wisdom to deal with that knowledge?'⁹

I have mentioned Erwin Chargaff before. He was a distinguished professor of biochemistry at Columbia. His researches, which he freely shared with Crick and Watson, led to what are known as Chargaff's rules, which made the discovery of the structure of DNA possible. He noted how extraordinarily different the world of science had become during his lifetime:

The world of science was open before us to a degree that has become inconceivable now, when pages and pages of application papers must justify the plan of investigating, 'in depth', the thirty-fifth foot of the centipede; and one is judged by a jury of one's peers who are all centipedists or molecular podiatrists. I would say that most of the great scientists of the past could not have arisen, that, in fact, most sciences could not have been founded, if the present utility-drunk and goal-directed attitude had prevailed. ¹⁰

He writes of a real fear that seems to me well-grounded: that there is no vision of what we are doing in science, and that, most worryingly, our inevitable ignorance of all but a small part has been forgotten. He relates this to changes in the way we think: from a broad, creative process in which the open pursuit of knowledge for its own sake was valued, to the narrow, deterministic, 'utility-drunk' and 'goal-directed' attitude of the left hemisphere mindset. In Carse's terms what should be an infinite game, has become a finite one. Chargaff likens the effect to the piecemeal destruction of a great work of art:

The wonderful, inconceivably intricate tapestry is being taken apart strand by strand; each thread is being pulled out, torn up, and

analysed; and at the end even the memory of the design is lost and can no longer be recalled.¹¹

He continues that there has been

an outright change in the types of individuals entering the various disciplines. Science has become a hard and pitiless and, what is even worse, a thoroughly humourless master ... The profound Lichtenberg [the eighteenth-century German physicist and philosopher] had taught me that for people to find something they must first know that it exists. This was an assurance that I have never lacked during my entire life. What became weaker as I grew older was the conviction that the way of searching which we had chosen was the right one. The feeling that there is always more than he can find, that he is only pulling shreds out of an unfathomable continuum, forms part of my definition of a scientist. ¹²

He comments that in the world in which young people now have to learn science, keeping in with one's boss and following fashion are so important that 'a few of these young people may, in the course of their apprenticeship, become scientists, but most never will. They will turn into specialists.'¹³ And, he observes, specialism drives the scientific disciplines further and further apart, as well as leading to 'an enormous rise in the costs required to maintain and expand the scientific establishment, with a concomitantly increasing gap between claims and achievement.'¹⁴

Chargaff lamented what he called the 'overfragmentation of the vision of nature – or actually its complete disappearance among the majority of scientists'. In its place was

a Humpty-Dumpty world that must become increasingly unmanageable as more and tinier pieces are broken off, 'for closer inspection', from the continuum of nature.¹⁵

It is salutary to remember that much great science of the past was done by people who were broad-ranging thinkers, often working alone, and often

outside the walls of any academic institution. Even into the modern era, three of its intellectual giants, whose influence ranges well outside of any speciality – Darwin, Freud and Einstein – did the work for which they are mainly remembered alone, and often without the support (or the straitjacket, depending on how you look at it) of conventional academic institutions.

It is worth noting also that, like other intellectual giants such as Russell, Whitehead and Wittgenstein, much (indeed, with the exception of Einstein, almost all) of their influence comes, not through papers, but through lectures or books. A book gives time and space for ideas to be properly developed. The scientific paper, in particular the conventional contemporary science paper, is best suited to the dissemination of data, rather less well to the exposition of seminal ideas, though it does happen. Nowadays career scientists don't write books. Books have no career value, because they have no 'impact factor' associated with them, and they take (or should take) a long time to write, time which could be more usefully applied to producing papers. The parts are more valuable than the whole: salami slicing rules. What counts, as usual, doesn't get counted.

Furthermore, books are also likely to be addressed to the 'laity', which as I say turns out to be anyone – even another scientist – not specialising in whatever area is under discussion: and 'how can *they* be expected to understand real science'? My worry is that even the descriptions of human behaviour on which neurology, psychiatry and psychology depend are becoming further and further from any experience of a human being, and as a result further and further from the purview of an intelligent non-specialist reader. As the reader of Part I will know, the in-depth case studies of the early twentieth-century German and French literature, particularly, provide fascinating insights into human experience that leap from the page – treasure troves of, at the same time, both detailed information and a broad human understanding. Even research papers written in the 1970s and '80s, and well into the 1990s, seem for the most part, to be written for a human being, and understandable by any intelligent reader with a basic science background. At some point in the last 20–30 years, however, that sense has been lost. The terminology is a significant part of the problem. All human description but the most limited kind is excluded: subjects are selected by the application of a 'tool', the 'cohort' is put through a scanner, and the data then submitted to computer analysis, the technical data on this replacing any account of human behaviour or experience. Increasingly, the heavily

acronymic jargon of research papers seems to me to present an almost impenetrable barrier to anyone other than the most highly specialised reader, and even then, if they are to get anything out of the exercise, they must have a huge capacity to tolerate boredom.

An analysis of the language of research publications over time confirms my impression that there is what the author calls a ‘drift towards inaccessibility’ that took off in the last decades of the twentieth century:

The broad consequences are that ideas flow less freely across and within the sciences, and the public’s access to (and maybe trust in) science is diminished ... To scientists this trend represents a narrowing of their range of expertise, even while the depth of their knowledge grows. So they may change specialities less often as the costs of becoming expert in another area grow ... This erection of higher and higher barriers to the comprehension of scientific affairs must surely diminish science itself. Above all, it is a threat to an essential characteristic of the endeavour – its openness to outside examination and appraisal.¹⁶

And that was just in 1992, some 30 years ago.

Of course I am particularly concerned with neuroscience; and it is a problem that today’s neuroscientists and psychologists are themselves increasingly focussed on mechanisms and increasingly unused to seeing what they do as having much to do with *persons*. Yet, if you stop thinking of the brain as just a mechanism, it becomes possible, once more, to see it for what it most assuredly is: part of a person. In an era that, at least in name, embraces embodied philosophy, that should be a very important step. In the film *The Divided Brain*, Michael Gazzaniga says of *The Master and his Emissary*: ‘This book is taking a selected set of neuroscience findings and trying to relate them to the clinical psychiatric experience, telling us a story that tries to mesh those two things. I’m not comfortable with that.’ What is implied by the word ‘selected’ is another matter (there are over 2,000 findings referred to). But what is surely fascinating is that a prominent research psychologist, working on how the brain functions in a lab, should not be comfortable with relating brain research to actual *people* with brain conditions outside the lab: what he calls ‘clinical psychiatric experience’. Such research is *ipso facto* ‘related’ to real people. I had,

further, assumed the point of such research was to apply it to their benefit, if not at least to help us understand Plotinus's question, 'who are we?' Or as the great neurosurgeon Wilder Penfield put it: 'The problem of neurology is to understand man himself.' Gazzaniga continues: 'I think here's how you think about it. The brain is as mechanical as clockwork ... Let's just get over that – that's the way it is.'¹⁷

I am reminded of the words of Jonas Salk, when asked about how brain science can help us understand the world and lead better lives: 'It's in the human dimension, as distinct from the molecular-cellular, if I could make this contrast, trying to understand the whole, which is far greater than the sum of the parts. That is where I sense the need for a new kind of mind, for individuals who are integrators, as distinct from the reductionists, or reductionists who could integrate as well.'¹⁸

One sees many factors here that do indeed align with the hemisphere hypothesis: narrowness, technicalisation and fragmentation, at the expense of breadth, humanity and synthesis; the familiar at the expense of the original; a suspicion of all forms of judgment based on quality, and their replacement by those based on quantity; and we will see more as we go on.

Unfortunately, many scientists are not comfortable with philosophy. They see it as an area in which they cannot have precise answers and access to the 'truth'. That there could be a place where they might have certainty is, of course, an illusion, as I have emphasised. And not only can science not divorce itself from philosophy, but it doesn't get closer to the truth by the attempt. Quite the reverse.

It is all too understandable that scientists don't want to think philosophically about what their research tells us. But they can't avoid it. And because they can't avoid it, but too often don't think about it, they impose a default, naïve form of materialism on anyone who will listen. It seems to be assumed that, just because someone is a good astrophysicist or evolutionary biologist, that fact in itself qualifies him or her to lay down the law on subjects such as the existence or otherwise of a God. 'Now that science has most successfully resisted theology', wrote Nietzsche,

whose 'hand maid' it was for too long, it is now, with great high spirits and a plentiful lack of understanding, taking it upon itself to lay down laws for philosophy, and for once to play the 'master' – what am I saying? to play the *philosopher* itself.¹⁹

HOW RELIABLE IS SCIENTIFIC EVIDENCE?

Good scientists themselves do not make the sorts of claims for certainty that are sometimes made on their behalf.

Preliminary remarks on neuroimaging

Clearly the argument of this book depends on research into the brain: increasingly brain research relies on forms of functional neuroimaging, from which much useful information can be gathered. As one might expect, it has its strengths and weaknesses. Since knowing how it can inform and how it can obfuscate is central to the way we should evaluate it, I cannot avoid some brief preliminary remarks on the topic. Then I will turn to the issue of reliability more generally in science.

Scanning generates hugely complex data sets. There are understandable problems involved in the interpretation of such data sets by software packages. It was suggested in a much publicised paper in 2016 that ‘a bug in software’ might have invalidated 15 years of fMRI (functional magnetic resonance imaging) research.²⁰ The point at issue was that such packages carry out over 100,000 independent statistical tests on the results, inflating the number of false positive results. That is to say, if you do enough comparisons, you will find some that come up trumps by chance alone.

However, the suggestion that this problem goes mainly uncorrected is not accurate. Certainly one published rebuttal suggests that the claim is based on an erroneous conclusion about the resting state with which results are conventionally compared, and provides ‘no basis to question the validity of the thousands of published fMRI studies that have corrected for multiple comparisons or the commonly employed methods to correct for multiple comparisons’.²¹

Whether that is where the matter rests, or not – and I suspect it is not the end of the story – only time, and the debate of expert statisticians, will decide. The point I am making is that, in a healthy science, such debate is intrinsic to the process of science; and which are the correct inferences to draw from complex computer-generated data sets is not above such debate.

Structural imaging of the brain is more or less unimpeachable: it effectively enables one to conduct a living post-mortem. Though what to make of one's findings may be problematic (an abnormally enlarged region may be as dysfunctional as one that is abnormally reduced in size, for example), what one is seeing is not. As a research tool, *functional* imaging, however, is fraught with difficulties; and wherever there is another source of information about brain function, functional scanning should be treated in concert with it, as providing, at best, confirmation. And when it is in conflict with other sources of information, we should be appropriately circumspect. This is because interpretation of such data is peculiarly uncertain, for a number of reasons.

Experimental science often takes not just data and ideas out of context, but takes people out of one context and puts them in another. Many lab situations are extremely unusual contexts from which to generalise. Lying in a scanner is one of them. 'It is known that changes in experimental conditions can lead to large changes in the patterns of regional metabolic activity', writes Bruce Wexler, a proponent of positron emission tomography (PET), a type of functional metabolic imaging; adding that 'with this in mind I must note that special and unusual conditions are unavoidable concomitants of all PET studies.' Small variations in the way the task is presented may make a large difference to the results. Changes in novelty or complexity can mask relevant structures – or falsely identify irrelevant ones.²² Subtraction paradigms, where two sets of conditions are compared so as to isolate the element of interest, are associated with their own problems.²³

And there's more. Functional imaging is deceptively attractive because it appears to localise: that is much of its appeal. But for a number of reasons outlined earlier [*schizophrenia and autism ch – search Monakow*], the brain does not function in local modules but in widely distributed networks. An area that 'lights up' hides as much as it reveals. In Elkhonon Goldberg's phrase,

trying to surmise the brain activation pattern of a cognitive task based on functional neuroimaging data may be like Noah trying to surmise the landscape of Mesopotamia after the Great Flood by staring at the peak of Mount Ararat protruding above the water.²⁴

One cannot assume that the areas that ‘light up’ are those fundamentally responsible for the ‘function’ being imaged, or that areas that do not ‘light up’ are not involved.²⁵ Areas that show activity may be doing so in *response* to activity somewhere else in the brain which is not showing up, but is the primary link with the activity in which we are interested. Metabolic activity may be great in one part of the system, eg, in the basal ganglia, because this is a regulatory constituent of a system whose other parts (neocortex) are where the activity we are interested in measuring is probably best understood as ‘going on’. Wexler continues that ‘the assumption is that areas with increased or decreased metabolic activity are in some ways dysfunctional (areas with normal metabolic rates might also be dysfunctional)’:

These uncertainties can be illustrated by analogy with the fuel consumption and electrical activity in an automobile. In a car a variety of functional changes can result in similar levels of fuel consumption. A total lack of fuel use is consistent with mechanical failure, but could also result from a sick or vacationing driver who never starts the car. Increased fuel consumption could be found in a high-performance sports car, a poorly tuned old clunker, or an ordinary car moving at normal speed with an emergency brake on. A change in electrical patterns could be due to the use of windshield wipers or defrosters, the activation by loss of oil of an indicator light, or use of the audio system.²⁶

Imaging has become more sophisticated since this was written, but most of these considerations are still as applicable, since data still require *interpretation*: it can’t just be ‘read off’ in some assumed to be objective, and therefore truthful, fashion.

A further complication is that only effortful tasks tend to register: this means that the more expert we are at something, the *less* we will see brain activity. An expert will show lower levels of activation than someone unfamiliar with the task: equally a part of the brain that is normally not particularly significant in a certain task may show up as ‘highly active’ if, for reasons of experimental design or brain abnormality, it ends up inexpertly dealing with it. In keeping with this, people with higher IQs have

lower cerebral metabolic rates during mentally active conditions;²⁷ as do those with bigger brain size,²⁸ which is also correlated with IQ.²⁹ If you allow yourself to take in the full import of this principle, a degree of hesitancy should encumber naïve enthusiasm.

We have, too, to remember that the activations we visualise in the brain may actually be inhibitory in nature – inhibition may be indistinguishable from activation using current fMRI methods.³⁰ That's a pretty important distinction when it comes to interpreting what you see: especially in the human brain, where, as we saw in Chapter 1, so much activity is inhibitory.

As if that is not enough, many variables are involved in any experiment involving human beings. Male and female subjects respond differently – so differently, in terms of laterality, as we have seen, that it may destroy the validity of findings by suggesting a null result where the reality is that there are significant, but opposite, lateralising tendencies between sexes which, once aggregated, cancel one another out.³¹ Not only left- and right-handedness may make a difference, but more importantly, strongly lateralised handedness (whether right or left) may give a quite different picture from more mixed handedness; race and age also make differences. Individual cases may be different because the way we experience the world individually is different; even the same brain varies in its response to the same task depending on the context – for example, what's happened previously.

The upshot of all this is that many studies lack statistical power to reach the conclusions they would like to claim. This is of especial relevance to *brain laterality*. On top of the problems already mentioned, according to Nikki Marinsek and colleagues,

neuroimaging studies may especially fail to shed light on hemispheric lateralization: contrasts designed to find the neural correlates of one process may be contaminated by the neural fingerprints of another, which may in turn make a truly lateralized process appear bilateral. We also necessarily make the neuroimager's fallacy in almost every case, as the vast majority of studies – even those that report lateralization results – only report clusters of activation, not direct contrasts across hemispheres.³²

In any case, activity in both hemispheres doesn't make the contribution equal. It depends what the activation signifies. Whenever you start a car engine, the fan comes on, but it doesn't propel the car.

Scanners require task simplification, and the more the task is simplified, the less it is like anything that happens in the real world. Yet the more complex the task, the more widely distributed the networks involved are likely to be, and the harder it will be to know what it is that one is measuring, and how it correlates to any one human activity. And broader activation brings a further problem. If one hemisphere makes a limited contribution to a process, but shows a single persistently activated area throughout a scan, it will falsely appear much more strongly correlated with the activity than the other hemisphere, in which, though the involvement covers a much larger area, the focus of maximum activity continually varies. No one focus in this hemisphere will seem as correlated with the activity in question as a much less significant (but confined and persistent) focus appearing in the other hemisphere. This is especially true where the results from numerous studies are aggregated in an attempt to locate the 'key' area.³³

Hence the vitally illuminating power of deficit literature – studies of those who have an acute loss of one hemisphere's input to a process, through stroke, injury or tumour – to reveal the individual contribution of one brain region at a time. Such studies tend to be more consistent, as you might imagine, than neuroimaging literature.³⁴ They have their problems, too, and they cannot avoid some of the same issues that bedevil the imaging literature; but almost all the drawbacks to lesion studies tend in the direction of false negatives – missing something that is there – not false positives – finding something that isn't; so that when you find a clear result, repeatedly, it is relatively reliable. And it is now possible experimentally to suppress for a while a particular hemisphere or part of a hemisphere, and observe what happens to the person whose brain it is. It is true that Hughlings Jackson warned that 'to locate the damage which destroys speech and to locate speech are two different things'.³⁵ But there were no scans in his era, and this criticism of simple mapping applies, *mutatis mutandis*, to all localisation techniques, most particularly to functional imaging: seeing a spot on a scan 'light up' when you speak is, also, not to locate speech. As Justine Sergent cautioned, the benefits of functional neuroimaging 'should not mask its inherent limitations nor the risk of

promoting a modern type of phrenology that would disregard evidence of interactive and distributed processing carried out in cerebral structures'.³⁶

The long and short is that lesion studies are a vital ingredient in a mix which includes imaging studies and EEG studies of normal brains, and a combination of approaches is best.³⁷ To quote one prominent neuroimaging specialist: 'Some people believe that psychology is just being replaced by brain imaging, but I don't think that's the case at all ... It's the confrontation of all these different methods that creates knowledge.'³⁸

Replication of results

Now to turn to more general considerations applicable to science research across the board. A large collaborative study published in *Science* in 2015 found that repeating experiments in psychology produced significant results in only half of cases, with the combined results yielding a significance rate of 68%, down from 97%.³⁹ Given how complex and variable human beings are, this is not too surprising, but it is worth bearing in mind. The study concluded that results were generally unreliable, because not easily reproducible. However, a subsequent response in *Science* claimed that this paper itself contained three statistical errors, and that it 'provides no support for such a conclusion ... the data are consistent with the opposite conclusion, namely, that the reproducibility of psychological science is quite high'.⁴⁰ To which the original research team responded by suggesting that 'both optimistic and pessimistic conclusions about reproducibility are possible, and neither are warranted'.⁴¹

You might be forgiven for thinking that this result illustrates the difficulty of measurement specifically in psychology. But that is not the case. Two of the best-known analyses, from psychology⁴² and cancer biology,⁴³ found reproducibility rates of around 40% and 10%, respectively. A survey of 1,576 researchers across scientific disciplines published in *Nature* revealed that more than 70% of researchers had tried and failed to reproduce another scientist's experiments, and more than half had failed to reproduce their own experiment.⁴⁴ In fact, more than half thought there was a significant crisis in research reproducibility and only 3% thought there wasn't a crisis at all. Yet 73% nonetheless went on to say that they thought that at least half of the papers in their field could be trusted, with physicists

and chemists generally showing the most confidence. And although the vast majority of respondents had failed to reproduce an experiment, less than 20% said that they had ever been contacted by another researcher unable to reproduce their work. The results of this study were ‘strikingly similar’ to another online survey of nearly 900 members of the American Society for Cell Biology.⁴⁵

Take something about as far removed as can be from human biology – the measurement of fundamental physical constants, such as the speed of light (c), the Planck constant (h), and the gravitational constant (G). According to Henrion & Fischhoff,

assessing the uncertainty due to possible systematic errors in a physical measurement unavoidably involves an element of subjective judgment. Examination of historical measurements and recommended values for the fundamental physical constants shows that the reported uncertainties have a consistent bias towards underestimating the actual errors. These findings are comparable to findings of persistent overconfidence in psychological research on the assessment of subjective probability distributions.

They conclude: ‘The underestimation of uncertainty in measurement of physical constants and compilations of recommended values seems to be pervasive.’⁴⁶

One might assume that, while replication was an issue across the board, it was much less likely to affect widely cited work published in the more prestigious journals. But is that a valid assumption?

A problem for the general public is that the heavy-hitting articles with catchy titles make headlines in the popular press, while the more measured responses, that create a more nuanced picture, do not. So the public is served up two competing fantasies: that anything that comes from science is irreproachable, and that most of it is irredeemably flawed. This kind of polarisation makes rational debate about the true (therefore limited) value of science very difficult indeed.

Marcus Munafò, a biological psychologist, and Jonathan Flint, a prominent geneticist, warn that genetic ‘breakthroughs’ in medicine are often nothing of the sort. The discovery of genes for depression or

schizophrenia – or for happiness – get good press coverage, usually based on publication in a respected scientific journal such as *Science* or *Nature*. Less prestigious journals often subsequently publish reports that contradict the original claim, some suggesting that the findings are quite compatible with chance. These reports, usually with larger samples, are rarely newsworthy.⁴⁷ On the face of it unexpectedly, the authors found that studies published in journals such as *Nature* or *Science* with a high ‘impact factor’ (IF), a measure of the frequency with which the average paper in a journal is cited in a year (typically taken to indicate higher prestige or quality), are less likely to give an accurate estimate of effect size than those published in journals with a lower impact factor.⁴⁸

To the credit of science, one of the most cited papers in the last decade of science publishing is by a professor of medicine and statistics at Stanford called John Ioannidis.⁴⁹ Its title, ‘Why most published research findings are false’, gives an inkling of its conclusion. Its point is that much – apparently most – research is not adequately designed to prove what it claims to show. Many studies in the area of neuroscience, for example, will miss genuine effects, and ‘find’ false effects, because of low statistical power. This is partly a result of the huge expense involved in carrying out scanning studies on a large scale.⁵⁰ Yet, of course, spending less (but a still not inconsiderable amount) on producing invalid data is a waste of time, money and human effort.

Ioannidis casts light on the see-sawing of research findings that we have observed. ‘The hotter a scientific field (with more scientific teams involved), the less likely the research findings are to be true’, he warns:

With many teams working on the same field and with massive experimental data being produced, timing is of the essence in beating competition. Thus, each team may prioritise pursuing and disseminating its most impressive ‘positive’ results. ‘Negative’ results may become attractive for dissemination only if some other team has found a ‘positive’ association on the same question. In that case, it may be attractive to refute a claim made in some prestigious journal. The term Proteus phenomenon has been coined [by Ioannidis himself] to describe this phenomenon of rapidly

alternating extreme research claims and extremely opposite refutations.⁵¹

Ioannidis continues, with a further point that is ethically more troubling, but will hardly surprise anyone who understands human nature: ‘the greater the financial and other interests and prejudices in a scientific field the less likely the research findings are to be true’. He continues:

Many otherwise seemingly independent, university-based studies may be conducted for no other reason than to give physicians and researchers qualifications for promotion or tenure. Such non-financial conflicts may also lead to distorted reported results and interpretations.⁵²

Publication in a learned journal brings a huge temptation. Those who have published breakthrough results in prestigious journals get offered extremely attractive packages at major universities. This process has ‘cut a swathe through scientific thinking like a forest fire, turning our thoughts and efforts away from scientific problems and solutions, and towards the process of submission, reviewing and publication.’⁵³ In order to achieve this desirable outcome, researchers may keep analysing the results in slightly different ways (known as ‘data mining’) until they get a significant *p*-value (a measure of statistical significance, conventionally less than 0.05). This makes one’s research much more likely to be published.

Though this is misleading, it is more what would normally be considered a misdemeanour than actual fraud. Yet its cumulative impact may be great. In a survey of 3,200 scientists, 33% said they had engaged in at least one of the 10 most common research ‘misdemeanours’ during the previous three years.⁵⁴ Since this finding is based on a questionnaire survey, with a response rate of about 45%, the figure may be a serious underestimate, since more corrupt scientists are less likely to participate in a survey of this kind. Another study which involved inducements to be honest, found that ‘even raw self-admission rates [frank admissions of guilt] were surprisingly high, and for certain practices, the inferred actual estimates approached 100%, which suggests that these practices may constitute the *de facto* scientific norm’.⁵⁵ Ginny Barbour, a senior editor

with the *PLoS* group of journals, reports that one-third of authors could not find the original data to back up figures in scientific papers when these were questioned.⁵⁶

Turning to recognisable fraud, in 2012, the *BMJ* reported that a survey of more than 2,700 researchers showed that

one in seven UK-based scientists or doctors has witnessed colleagues intentionally altering or fabricating data during their research for the purposes of publication ... 13% of these researchers admitted knowledge of colleagues 'inappropriately adjusting, excluding, altering, or fabricating data' for the purpose of publication ... The *BMJ* has been told of junior academics being advised to keep concerns to themselves to protect their careers, being bullied into not publishing their findings, or having their contracts terminated when they spoke out.⁵⁷

THE PROBLEMS OF PUBLICATION

The pressure to publish or perish, typical of a world in which quantity is more important than quality, and where, if it can't be measured, it isn't real, means that universities insist that their academic staff produce papers, whether or not they have anything to say. This process is inimical to free thinking, a topic to which I will return. Scientific *thinking* gets crystallised too early, before it has had a chance to broaden and deepen; there is no longer a chance for ideas to evolve, to enter the necessary fallow period of unconscious gestation, without being prematurely forced into explicit form, and worse still in sliced form, so that what might have come to be a dawning new *Gestalt* is forever lost. And in the end, science is not about producing data so much as *thinking*, to which the acquisition of data can be only a prelude or addendum. This seems sometimes to be forgotten.

But the pressure also skews science badly. Positive findings are considered more prestigious than negative ones, which are, however, equally valuable and equally significant. It is much harder to get negative outcomes – such as finding that a medical intervention does not work – published (unless it is a non-mainstream intervention). Richard Smith, former editor of the *BMJ*, claims that as a result it is 'clear that authors often do not even bother to write up such studies. This matters because it biases the information base of medicine.'⁵⁸ In 1998 a review of trials published in England found that only one in four did not give positive results. More troublingly, not a single trial published in China or Russia (and across the former USSR) found a test treatment to be ineffective.⁵⁹

Pressure results in corners being cut, and claims being inflated. According to Cambridge biologist Peter Lawrence, what you need to do in order to succeed is

hype your work, slice the findings up as much as possible (four papers good, two papers bad), compress the results (most top journals have little space, a typical *Nature* letter now has the density of a black hole), simplify your conclusions but complexify the material (more difficult for reviewers to fault it!) ...⁶⁰

The result is the usual effect of hypertrophic growth: it becomes harder and harder to cut a path through the tediously luxuriant thicket of science publishing to find the clearing where truly excellent, thoughtful science resides.

The way in which research is now evaluated corrupts the data and is a fertile source of confusion on its own. It is also incidentally just another example of how when we try to introduce ‘objective’ measuring systems, we often make things worse than allowing people to use their judgment. The impact factor has become an omnipresent distorting factor. As we have seen, journals with higher IF have been found to be less reliable than some of those with a lower IF. But that’s just the beginning. If a journal publishes few articles, but one of those gets to be cited many times, the IF is immediately raised.⁶¹ The process is inevitably open to corruption. For example, a journal could commission a literature review on a topic that was dealt with by an earlier publication or publications in the same journal. This would result in its articles being repeatedly cited, with the result that its IF is artificially inflated.⁶²

According to Peter Lawrence, ‘the use of both the H-index [an alternative to IF] and impact factors to evaluate scientists has increased unethical behaviour: it rewards those who gate-crash their names on to author lists.’ Being a name on a paper does not require that you are more than dimly aware of the research. This has the advantage that when a paper is heavily criticised you can claim distance, something that, as Lawrence tartly points out, has never been pleaded when it is time to dish out the prizes.⁶³

The IF also exerts a baleful influence on journal content in other ways. Case reports, which were once the lifeblood of medical journals, are seldom published these days, except as occasional letters. The point is that case reports, by their nature, deal with rare events, which means they are less likely to be cited than other types of article, and so, it is feared, will drag down the IF.⁶⁴ This leads to a huge impoverishment in the field of medicine, as one can easily discover by going back into the beautifully detailed journal reports of an earlier era, and comparing them with the thin aggregated data from subjects who have been selected by an assessment tool, put through a scanner, and then subjected to an array of statistical tests. Note, though, that – yet again – this is not an ‘either/or’ matter. We need

both kinds of study, not just one. At the moment the former kind is an endangered species.

The primary purpose of the IF may be to rank journals, but it is now often used as a proxy measure to evaluate the quality of individual researchers. This is bad enough, but remember it is not even the impact factor of the researcher's paper that is counted, but that of the journal in which it was published. The actual paper may prove to have been a waste of many people's time, but it will still count favourably towards getting the next job. The need to publish in high-IF journals may force researchers to do their work in already 'highly populated' areas of science, as there is a readily available, large cohort of fellow researchers in the same field, who could potentially cite each other's works (even if only negatively), as has been recently pointed out.⁶⁵ To coin a phrase, in science there is only one thing worse than being talked about, and that is not being talked about.

But being cited doesn't mean being read. The pressure to produce paper after paper means that other papers are often cited without the citation even being verified, never mind the paper, or even the abstract, read. Occasionally, as I have discovered after looking it up, the main finding of a cited paper was the precise opposite of the one it has been repeatedly cited in the literature as offering. Peter Lawrence estimates that of the 48 citations of one of his papers, only eight were appropriate, 37 being irrelevant and three plain wrong.⁶⁶ It is estimated that only 20% of cited papers have actually been read, where the word 'read' means 'at the very least consulted a trusted source (eg, the original paper or heavily-used and authenticated databases) in putting together the citation list.'⁶⁷ (For the record, I did read the paper: I even went so far – my preferred method – as to read it in the more conventional sense, though I cannot claim to have understood all the statistical formulae.) The authors of the paper looked at propagation of misprints by blind copying, and found one misprint that 'propagated' in the literature 78 times. I have found numerous others, which are occasionally adverted to in the notes throughout this book.

And sometimes it's not even a matter of laziness – more like desperation. With disarming honesty, one of the authors of a paper on melanism in fish included the remark, 'Should we cite the crappy Gabor paper here?', a comment which slipped undetected into the published article.⁶⁸

A whole new level of unreliability has been reached through a process whereby authors pay to have their work published. This is well-intentioned, in that it puts the burden on (the institution of) the researcher rather than the reader, enabling the journal to become ‘open access’. But since publishing a paper makes money for the journal, whereas declining it neglects an opportunity, it is clearly open to corruption. Some journals take papers for no better reason than because the authors pay to have them published: in China it is even possible to arrange to have your name put on someone else’s paper, or to have prestigious authors attached to your own, for a fee.⁶⁹

In 2014, Peter Vamplew, an Australian computer scientist, submitted a paper to the *International Journal of Advanced Computer Technology* after receiving dozens of unsolicited emails from the publication, and from other journals of dubious moral standards. The paper, entitled ‘Get Me Off Your Fucking Mailing List’, consisted simply of the seven words of the title repeated over and over again for several pages. Nothing else. He even added a helpful diagram:

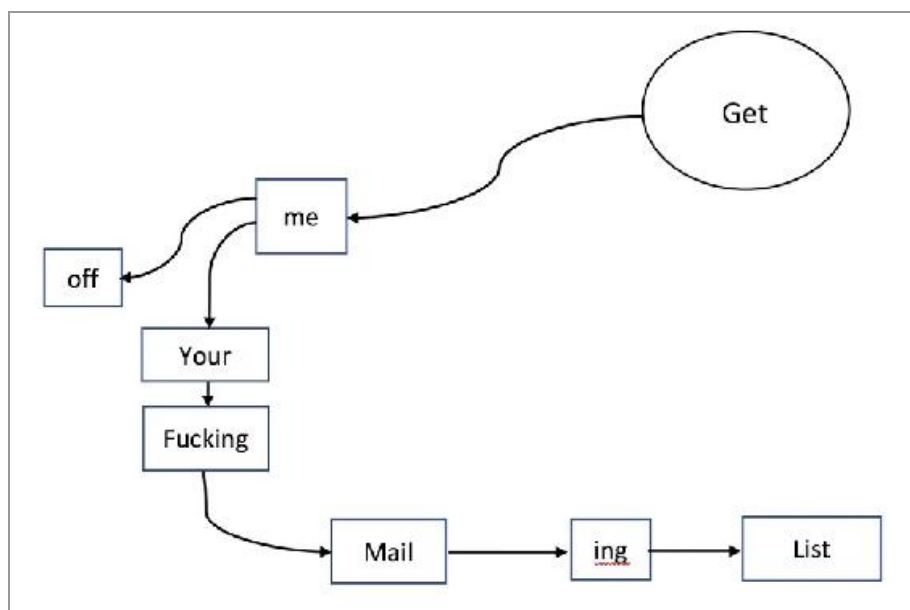

Fig. 33. ‘Flow diagram’ from spoof paper sent to International Journal of Advanced Computer Technology by Peter Vamplew, 2014

He expected that the journal’s editors would ‘read it, ignore it, and at best take me off their mailing list’. Weeks later, he received good news. It

was accepted for publication: ‘I pretty much fell off my chair.’ In line with the highest academic standards, ‘Get Me Off Your Fucking Mailing List’ had reportedly been subjected to rigorous, anonymous peer review. ‘They told me to add some more recent references and do a bit of reformatting’, he said. ‘But otherwise they said its suitability for the journal was excellent.’ Vamplew was required to pay a \$150 fee to have the paper published, but he declined. The scheme earned Vamplew some online recognition, but at the time of reporting, his main aim remained unfulfilled. ‘They still haven’t taken me off their mailing list’, he said.⁷⁰

An academic librarian at the University of Colorado, Jeffrey Beall, reported in *Nature* that up to 10% of open-access journals were exploiting the model by charging a fee to proofread, peer-review and edit a research paper without actually carrying out the work. His blog, entitled Scholarly Open Access, listed questionable, scholarly open-access publishers, that showed signs of being unethical or even predatory. By the time it closed down, it listed 1,155 publishing houses, with respectable-sounding names such as ‘Academic Research Journals’, ‘Scientific & Academic Publishing’, ‘Science and Education’, ‘Open Science Publications’, ‘International Science & Research Journals’, ‘Global Scientific Research Journals’, ‘Frontiers in Bioscience’ and ‘Advancements in Science’. On 15 January 2017, however, his blog was suddenly wiped clean and subsequently closed down. Initially he refused to say anything about the reason, but, according to the *Nature* blog,⁷¹ he later referred, in a piece for *Biomedica Medica*, to ‘threats and politics’. That piece makes gripping reading, and every reader of this book is recommended to read it in full.⁷² Arguing that ‘predatory publishers pose the biggest threat to science since the Inquisition’, and that ‘the once-proud scholarly publishing industry is in a state of rapid decline’, he attacks those at the heart of academe who connive at the destruction of scientific integrity:

facing intense pressure from my employer, the University of Colorado Denver, and fearing for my job, I shut down the blog ... I think that since the advent of predatory publishing, there have been tens of thousands of researchers who have earned Masters and PhD degrees, been awarded other credentials and certifications, received tenure and promotion, and gotten employment – that they otherwise would not have been able to achieve – all because of the easy article

acceptance that the pay-to-publish journals offer ... Universities in the United States are far along in the process of corporatizing themselves, and, in doing so, their public relations departments prefer that all university output be positive and aimed at attracting new customers, tuition-paying students. So if you are a faculty member at a university and you publish a blacklist, you will likely face much opposition and even harassment from the university, despite assurances of academic freedom ... Over the five years I tracked and listed predatory publishers and journals, those who attacked me the most were other academic librarians. The attacks were often personal and unrelated to the ideas I was sharing or to the discoveries I was making about predatory publishers ... Librarianship slavishly follows political correctness and trendiness ...

Beall's list importantly remains, at the time of writing, archived on the web.⁷³ That it is no longer live, however, means that publishers have no opportunity or incentive to improve their track record in order to get their name removed, and new journals can appear like mushrooms on a dunghill, with impunity. Beall, in a spirit of admirable transparency, lists his criteria for inclusion on the list,⁷⁴ but sadly he undermines his argument by including as one criterion, among many valid ones, the 'exclusion of any female members' on the board. Needless to say, that cannot possibly be a criterion of scientific integrity and in fact encourages science to become further mixed up with politics. That's how badly the waters of academic science are muddied. In his defence, perhaps he would not just have had to fear for his job, but would actually have lost it had that criterion not been included. (Perhaps if I had one, I'd lose mine for pointing this out.)

The same corrupt model may operate in 'selecting' speakers for profit-seeking conferences. Christoph Bartneck, an IT lecturer from New Zealand, knows, by his own account, next to nothing about nuclear physics, but decided to submit the abstract of a paper for consideration to the International Conference on Atomic and Nuclear Physics to be held in Atlanta, Georgia, in 2016. The paper was accepted. How on earth did he manage that? Simple. He got the autocomplete function on his iPhone to compose nonsense sentences, which he would trigger with a vaguely appropriate word. A typical sample follows:

Molecular diagnostics will have been available for the rest by a single day and a good day to the rest have a wonderful time and aggravation for the rest day at home time for the two of us will have a great place for the rest to be great for you tomorrow and tomorrow after all and I am a very happy boy to the great day and I hope he is wonderful.

He then sent it in under the name ‘Iris Pear’, a jokey reconfiguration of Siri Apple, complete with a fetching photo of ‘Iris’.⁷⁵ The fact that it was accepted within three hours of submission, along with a request for payment of a \$1,099 registration fee, tells you what you need to know.

Plagiarism is a further problem, but in practice hard to spot without much close scrutiny. As Charles Seife found out when he subjected the 16 papers in one issue of *Diagnostic Pathology* to detailed examination, and found suspicious irregularities in six of them,

the dubious papers aren’t easy to spot. Taken individually each research article seems legitimate. But in an investigation by *Scientific American* that analysed the language used in more than 100 scientific articles, we found evidence of some worrisome patterns [indicating plagiarism of language rather than results].

As one editor put it, ‘obviously, it’s a matter of great concern. I’m distraught to think of this going on and flooding the market.’⁷⁶

In some cases, the data are completely fabricated, as the case of a paper, published in the prestigious journal *Science* in 2015, and with the name of a world-renowned political science professor at Columbia attached to it, demonstrated.⁷⁷ But it’s not just, of course, in political science, which is inherently imprecise. Take, for example, anaesthetics, which is about as far as medicine gets from psychological human variables. Scott Reuben, while Professor of Anaesthesiology at Tufts, fabricated every clinical trial he reported over a prolific publishing career, and was jailed in 2009.⁷⁸ Joachim Boldt, another anaesthetist and a professor at Giessen, was suspended in 2010: 88 out of the 102 studies published by him over a 10-year period have now been retracted after data were found to be fabricated and other ‘ethical misdemeanours’ were found in his work.⁷⁹ But no-one quite

matches another anaesthetist, Yoshitaka Fujii, a former associate professor of anaesthetics at Toho, who was found to have falsified 183 papers, netting the world record for retracted science papers.⁸⁰ What is it about anaesthetists? I imagine that anaesthetists are no more corrupt than anyone else: it's just that they have long spells of boredom, which can be fruitfully employed in casting a critical eye over one's rivals' papers.

I remarked earlier that it increasingly seems that papers are not written for the human reader. This may be because they are not written by a human author. One of the most highly reputable science publishers in the world, Springer Verlag, had to withdraw 120 papers from its various publications after they were found, literally, to be gibberish that had been created by computer programs that simulate science writing.

Cyril Labbé, a computer scientist in Grenoble, went one better, and, as well as generating 102 fake papers, invented an author by the name of Ike Antkare (pun presumably intended), and entered them on Google Scholar, bringing the non-existent Antkare's H-index, a measure of productivity and impact, to 94, making him the 21st most cited scientist in the world.⁸¹

Of course such successful hoaxes are not confined to science. Indeed, it is particularly in the humanities that they first became notorious. I discuss some particularly nice ones in Appendix 2. The point is not that corruption is especially prevalent in science (although, to be entirely fair, that equally cannot be excluded, if only on the grounds that the intensity of competition to be first in achieving a 'breakthrough', the colossal available prestige, and the sheer volumes of cash at stake in such research programmes, act as potent inducements – none of which operate to the same extent in the humanities). No, the point is just this: that science is not *immune* from corruption on a fairly significant scale, and the significance is directly proportionate to the claims that are ritually made on science's behalf. After all, some science-naïve observers often seem gullible enough to believe that scientific pronouncements, *ipso facto*, represent 'the truth' with a capital T – not a problem usually experienced by authors of papers in the humanities.

In a sting operation, slightly differing versions of a deliberately flawed paper whose method, according to its author, should have been rejected by a high-school chemistry student, and whose results were meaningless, were submitted to 304 journals worldwide. The *majority* accepted it for publication, frequently asking for minor changes to format or layout. Only 36 of the 304 submissions generated review comments recognising any of

the paper's scientific problems. And 16 of *those* were accepted by the editors, despite the damning reviews. The fact that it came from a non-existent biologist, a Mr Ocorrafoo Cobange, at the non-existent Wassee Institute of Medicine in Asmara, didn't cause a hair to be turned.^{[82](#)} All of which leads to the question: what happened to peer review?

PEER REVIEW

Peer review may manifestly not take place, but at times even what appears to be peer review isn't. In November 2014 it was reported that

in the past 2 years, journals have been forced to retract more than 110 papers in at least 6 instances of peer review rigging. What all these cases had in common was that researchers exploited vulnerabilities in the publishers' computerized systems to dupe editors into accepting manuscripts, often by doing their own reviews. The cases involved publishing behemoths Elsevier, Springer, Taylor & Francis, SAGE and Wiley, as well as Informa... 'As you make the system more technical and more automated, there are more ways to game it', says Bruce Schneier, a computer-security expert at Harvard Law School's Berkman Center for Internet and Society in Cambridge, Massachusetts. 'There are almost never technical solutions to social problems.'⁸³

Nine months later Springer Verlag had to retract 64 articles in 10 journals, after an internal investigation discovered fabricated peer review reports linked to their publication. BioMed Central, an arm of Springer, retracted 43 articles when it found that researchers submitting a paper for publication had suggested suitable reviewers, but supplied contact details for them that actually routed requests for review back to the researchers themselves.⁸⁴

So peer review may be absent, or it may turn out to be self-administered. But what are we to think of peer review when it is functioning relatively normally? Few views are likely to be more informed than that of Richard Smith, since he is a scientist himself, and spent his life dealing with peer review as the editor of one of the most prestigious medical journals in the world, the *BMJ*. In a now famous article he drew attention to its pitfalls.⁸⁵ According to Smith, peer review is impossible even to define, and is 'thus like poetry, love, or justice'. For a start, he asks, who is a peer?

Somebody doing exactly the same kind of research (in which case he or she is probably a direct competitor)? Somebody in the same discipline? Somebody who is an expert on methodology? And what is review? Somebody saying ‘The paper looks all right to me’, which is sadly what peer review sometimes seems to be.

‘People have a great many fantasies about peer review’, he continues, ‘and one of the most powerful is that it is a highly objective, reliable, and consistent process’. Rather, he suggests, peer review is ‘a subjective and, therefore, inconsistent process ... something of a lottery’:

You submit a study to a journal. It enters a system that is effectively a black box, and then a more or less sensible answer comes out at the other end. The black box is like the roulette wheel, and the prizes and the losses can be big. For an academic, publication in a major journal like *Nature* or *Cell* is to win the jackpot.

How to assess peer review’s value? ‘The most important step on the journey was realizing that peer review could be studied just like anything else’, writes Smith. ‘At the time it was a radical idea, and still seems radical to some – rather like conducting experiments with God or love.’

A systematic review of all the available evidence on peer review concluded that ‘the practice of peer review is based on faith in its effects, rather than on facts’.⁸⁶ The evidence is that reviewers agree only slightly more than they would by chance, and that ‘sometimes the inconsistency can be laughable.’ Noting that it is ‘slow, expensive, profligate of academic time, highly subjective, prone to bias, and easily abused’, Smith points out that asking authors to pay for peer review, as they increasingly are, is ‘ironic’. Peer review, according to Smith, is

a flawed process, full of easily identified defects with little evidence that it works. Nevertheless ... scientists and editors have a continuing belief in peer review. How odd that science should be rooted in belief.⁸⁷

For hundreds of years during the great age of Western science, papers were reviewed by the editor or editors alone. Early attempts at a form of peer review in the nineteenth century already found that referees were soon overwhelmed, that the problem of bias was intractable, and that it had become an obstacle to scientific progress, because it made it almost impossible to say something not already accepted by the establishment. Outside Britain and America it was therefore not widely accepted till relatively recently. Indeed even there: *Nature* did not establish a formal peer review process until 1967. Of Albert Einstein's 301 publications there is evidence that only one underwent peer review (in 1932): 'interestingly, he told the editor of that journal that he would take his study elsewhere!'⁸⁸

The point about the laboriousness of the process – possibly worth it if it works, certainly not if it doesn't – reminds one of the physicist Leo Szilard's visionary satire, 'The Mark Gable Foundation', published in 1961. The story described the creation of an endowed not-for-profit foundation for the specific purpose of *slowing the pace of scientific progress*. The originator of this plan was a physicist who had emerged from a cryogenic coma 200 years into the future to find that most of his training was obsolete and that science was progressing altogether too fast. He therefore enlisted the help of the world's wealthiest man in creating a non-profit organisation to retard scientific progress.

His method of achieving this worthwhile objective was to create for each major field of scientific investigation a panel of distinguished scientists which would meet monthly to award prizes and grants for the best recent scientific work. This technique, it was explained, would keep the best of the older scientists away from their laboratories and busy with unproductive meetings and travel, and would cause the younger scientists in need of funds to go for the 'sure thing' which would be certain to lead to publishable results, thereby channelling research in the direction of the safe, the fashionable, and the obvious and away from more risky innovations and seeking for breakthroughs at the frontiers of knowledge.⁸⁹

'By going after the obvious', he wrote, 'pretty soon science would dry out. Science would become something like a parlour game ... There would

be fashions. Those who followed the fashions would get grants. Those who wouldn't would not.'⁹⁰

Peer review may be a real break on progress. A paper signed by 200 academics argued that, despite the potential benefits of peer review, 'the process of peer review can be prone to bias towards ideas that affirm the prior convictions of reviewers and against innovation and radical new ideas. Innovative hypotheses are thus highly vulnerable to being "filtered out" or made to accord with conventional wisdom by the peer review process.'⁹¹ A further serious problem is flagged up by the philosopher JL Auspitz: 'There are never peers to review unique work, and the very bureaucratisation of intellectual labour entrenches the conventional'.⁹² A process clearly inimical to science and the life of the mind – as is the extreme pressure put on scientists, *not* by the science establishment, but by the conventional press and academics in non-scientific subjects, who often know little or nothing about the research findings to date in the area, not to research, publish or even *discuss* areas in which it is feared findings might show their politically motivated beliefs to be unfounded. That, too, distorts what science can teach us.

The *BMJ* carried out several studies in which major errors were deliberately inserted into papers and then sent to many reviewers.⁹³ 'Nobody ever spotted all of the errors: some reviewers did not spot any, and most reviewers spotted only about a quarter.'⁹⁴ The studies concluded that peer review was not a reliable method of eliminating error or fraud, something of which we have already noted ample evidence. 'Robbie Fox, the great twentieth-century editor of the *Lancet*', Smith notes, 'joked that the *Lancet* had a system of throwing a pile of papers down the stairs and publishing those that reached the bottom.'⁹⁵

It is also obviously a process that is open to pretty gross bias. As science research has shown, the same paper with high-recognition names attached may be accepted for publication, when without them it is rejected.⁹⁶ Worse, papers by prestigious authors previously accepted may be turned down when re-presented to the *same journals* with unknown names and institutional affiliations. In one famous study by Steve Ceci and Douglas Peters, 12 papers from prestigious institutions, papers that had already been published, were faithfully retyped, except that the names of the authors and institutions were changed to fictional ones, such as Dove Ceters (a

conflation of the researchers' names) from the 'Northern Plains Center for Human Growth and Potential'. The papers were then resubmitted to the same journals that had first published them.⁹⁷

Of the sample of 38 editors and reviewers, only three detected the resubmissions. The other nine out of the 12 articles continued to receive evaluation, and eight of those nine were rejected; 16 of the 18 referees recommended against publication and the editors concurred. The grounds for rejection were in many cases described as 'serious methodological flaws' (remember, these were papers from prestigious institutions already published *in the same journals*). Elsewhere the authors comment:

None of the twenty reviewers who recommended rejection even hinted at the possibility that a manuscript might be acceptable for publication pending revision or rewriting. These findings were a convincing demonstration of the unreliability of peer-review.⁹⁸

Since by 1982 the correlation between dollars granted to institutions and the numbers of biomedical publications was already 95% (it is higher today), this corrupt process has a serious impact on research.

Funding which is so crucial for various types of research is available only in greatly reduced amounts to individuals at low status institutions. In the long run these individuals end up teaching heavier loads and having less graduate and undergraduate support to aid them in their research interests ... These data, however, provide absolutely no support for the belief that federal tax dollars are best spent by awarding grants to researchers at the largest and most prestigious universities.⁹⁹

For saying this, the researchers could not go unpunished.

Upon collection of the data we entered a period lasting approximately two years during which we experienced an intense and negative reaction from many powerful individuals in our profession for having conducted our study. One editor in the study wrote a letter threatening a lawsuit ... Other negative repercussions

included several threats to professionally censure us, and threats to reject the work of our colleagues, supposedly because they had been part of a department that had approved such ethically bankrupt research ...

‘Obviously’, they continue, ‘the journal review system has become a “sacred cow” to some’. They go on to describe how things unfolded:

These personal attacks took their toll ... Finally, after two unsuccessful attempts to publish our findings, replete with personally insulting *ad hominem* reviews, we found a publisher and positive reviews. Soon press releases were telling a diverse audience of our findings. Letters of support (over a thousand) came pouring in. Every one of them was complimentary ...¹⁰⁰

Ceci and Peters were not, however, alone. Canadian researcher Cannie Stark-Adamec had recently documented the successful resubmission of her own non-funded grant proposal to the same granting agency, unchanged except for the addition of a prestigious co-author and the tripling of its budget.¹⁰¹

Ceci and Peters were effectively whistle-blowers. It is worthy of note that those who act in defence of the proper principles of science are attacked by the corporate science establishment for being *traitors*. The only *traitors* here are those who are not faithful to science herself: their accusers. This kind of angry projection of your own failings onto others is almost always to be found when corporate employees blow the whistle.

Most worryingly, peer review is a process that is obviously open to fraud of the most heinous kind. Ioannidis writes: ‘Prestigious investigators may suppress via the peer review process the appearance and dissemination of findings that refute their findings, thus condemning their field to perpetuate false dogma.’¹⁰² It is clearly also possible to produce an unjustly harsh review to block or delay a competing publication and even to steal a competitor’s ideas:

Drummond Rennie tells the story of a paper he sent, when deputy editor of the *New England Journal of Medicine*, for review to Vijay

Soman.¹⁰³ Having produced a critical review of the paper, Soman copied some of the paragraphs and submitted it to another journal, the *American Journal of Medicine*. This journal, by coincidence, sent it for review to the boss of the author of the plagiarized paper. She realized that she had been plagiarized and objected strongly. She threatened to denounce Soman but was advised against it. Eventually, however, Soman was discovered to have invented data and patients, and left the country.

The reader might be forgiven for thinking Soman must have been a minor figure in an obscure institution. However, he had won a fellowship in endocrinology at the Yale School of Medicine, was appointed to its faculty the next year, and had publications in journals such as *Nature* and *The New England Journal of Medicine*. His senior collaborator on the paper under attack was Dr Philip Felig, a highly respected medical researcher, the occupant of an endowed chair and chief of endocrinology research at Yale. Lawrence suggests that ‘anonymous referees who murder papers for gain, who take advantage of privileged information or who share the contents of reviewed papers with others should be held to account’.¹⁰⁴ They rarely are.

Such human misdemeanours are not an indictment of science, any more than misbehaviour by clergy is an indictment of religion. But it complicates the idea that a paper’s having been peer-reviewed and published in a leading journal is a test of its integrity as science. And there is no other test available for most of us. Worse, since misdemeanours in the representation of science reflect not just on the moral stature of the individual but on the status of what is claimed in the name of science, they have a further toxic reach.

Attempts to improve the process by blinding reviewers to authors, making their names openly available to authors, and training reviewers have met with little success, as Smith reports.¹⁰⁵ What to put in its place? Research done at the *BMJ* itself indicates that having the value of a paper judged by the editor, or at least a small group of editorial staff, would be likely to produce just as good results, while obviously being much quicker, much less expensive, completely transparent, less open to malpractice, no more prone to bias, and no longer wasteful of the massive amount of potential research time currently lost to the process.¹⁰⁶ Impervious to any

such argument, the left hemisphere-dominated mindset insists that there is no viable alternative to the current system, and that it is working fine anyway.

This situation is reminiscent of science departments having to assess the ‘score’ of a researcher, rather than take the person they want. That is open to bias, certainly. But it’s not as if the alternatives are any less open to bias of other kinds. Bias is intrinsic to human life. We just waste a lot of time and money pretending we’re avoiding it, and then kid ourselves that the outcome was ‘objective’ – a more dangerous position, because it introduces complacency and is a much more difficult thing to fight, precisely because of its appearance of objectivity. As often in life, it is not what you know, but who you know that counts. Scientists are under pressure to show their faces at conferences, ‘network’ successfully there, befriend and make up to journal editors. Leaving your desk to network is, from the point of view of those who love science not the science institution, a dispiritingly rewarding career move.

And, just as in practice people will get on better with people they want to work with, a journal might have much more character if the editor chose what to publish. Competition means that someone who believes a paper chosen by the editor is mistaken will soon find another journal to accept their counterargument (or the same journal might well do so). A poor editor would soon find himself sitting on a depreciating asset, just as an employer who routinely made bad decisions would go out of business. And there would be more openness.

Serious scientists and science publishers are rightly concerned by the difficulty in policing a rapidly changing market in which trust has to an extent broken down, and in which pressures to succeed and inducements to distort truth or commit fraud are large. It is true that reports of gross fraud are not common given the vast number of articles published annually, but its full extent is clearly not known – we only hear about the cases that are exposed, and exposing deceit is hard compared with its commission.

The well-worn response that the problems are small and that being concerned about them is an ‘attack on science’ simply won’t do any more. Yet, naturally, one continues to hear it. An example is the contribution to *The Oxford Handbook of the Science of Science Communication* by Joseph Hilgard and Kathleen Hall Jamieson in which the media are blamed for an ‘attack on science’ in reporting publishing scandals, and in which the

authors recommend in future that such news be projected as examples of the success of science (supposedly succeeding in correcting itself). Nowhere in their piece is the true extent of the problem acknowledged or genuine concern about it expressed. Instead it is assumed to be a largely manufactured problem rooted in prejudice; instead of some serious soul-searching, we find only the usual symptoms of a failing establishment, defensiveness and complacency.¹⁰⁷ Meanwhile, those who defend science from bad scientists are, of course, to be treated as traitors.

PUBLIC HEALTH POLICY (SEE APPENDIX 3)

Finally here, let me very briefly address a slightly different question: how reliable is public health policy – advice on how to lead healthy lives? If the answer should turn out to be ‘not very’, this would be less damaging to the status of science itself as a path to truth, since it is less a matter of the reliability of the evidence, more of the uses to which it is put. However, it is still promulgated by scientists and scientifically trained officials who advise governments, so they cannot abjure responsibility altogether; and for most of the population it is the most obvious way in which the impact of the science establishment is felt in their lives.

I cannot report good news. Much of what is promulgated has little, or in some cases no, basis in evidence. The public would be deeply shocked if they knew the truth. On smoking, above all, and obesity to a great extent, it is generally reasonable and valuable; and there it has saved and will continue to save lives. But on fat, salt, alcohol and water consumption the distortions are so egregious as to court ridicule. At times, as I will point out, it has the potential to be actively damaging. I discuss the issues in Appendix 3, to which the interested reader is recommended. Overall we see in public health advice the hallmarks of the left hemisphere mindset at work: the triumph of theory over fact; denial when the evidence does not fit what one already just ‘knows’ to be the case; a refusal to see health in the round; disregard of context; cut and dried positions; and an obvious desire to control.

As readers of Appendix 3 will see, large vested interests badly interfere with objectivity. Industry funding of research distorts the publication of findings. It may be tempting to some to say that while behind these fallacious public policies masquerading as science there were financial pressures (eg, the sugar industry), pressure groups (eg, the anti-alcohol lobby), and a desire to fall in with received ‘wisdom’, even if it is received folly, none of this could operate in ‘real science’. But that would be complacent. Financial pressures operate throughout the world of academic science just as they do in public science. To begin with, and perhaps unsurprisingly, how much money is spent on a science project, and how many papers result from it, often substitute as measures of worth, skewing

the evolution of scientific thinking. Or big business can bully. The distinguished psychiatrist and psychopharmacology expert David Healy was offered a post as Director of Toronto's Centre for Addiction and Mental Health, and a Chair in the Department of Psychiatry at the University: after giving a lecture in which he suggested that fluoxetine (Prozac) might increase the risk of suicide, the offer was rescinded. Lilly, the manufacturer of Prozac, was a major contributor to the Centre at the time.

Since science is actually carried out by real people with all their complicated motivations, it is subject to all those human fallibilities, hardly peculiar to science, but from which science is not exempt. It would be kind, but wrong, to assume that no axes are being ground, and there's no boss to please, no prestigious grant to justify, no publication dependent on the outcome and no previously published views to vindicate. The fiercely competitive empires of ambitious academics involve huge grants on which they, their acolytes, and often whole universities depend for prestige and income. Only a very brave or foolish person will sacrifice a lucrative career by saying something unorthodox merely for the sake of scientific progress.

Such human corruption has nothing to do with the hemisphere hypothesis. But narrowness of vision, lack of creativity and imagination, excessive confidence in one's position and a tendency to get fixed in set ways of thinking potentially do – along with anger and denial when challenged.

TIME FOR A NEW PARADIGM?

Originality, branching away from the conventional path, challenging received wisdom, is the essence of good science. Without it, science fossilises: it loses intellectual power, and purchase on reality. Yet truly original work usually takes years to develop and years to be appreciated. To strike out in a new direction has everything against it from the personal point of view. Original thinking takes time – a lot of it – when, if it is to grow, it must not be crystallised too soon. It will be slower in emerging, more likely to be rejected by editors, and, if it gets that far, opposed by reviewers. It will take time to catch on – your ‘impact factor’ will suffer. Perhaps the most important paper in biology of the twentieth century, Crick and Watson’s paper on the double helix structure of DNA, which appeared in *Nature* in 1953, was cited rarely for the first 10 years, and indeed the number of citations actually declined over time (from about seven in the first year).¹⁰⁸ Ernest Rutherford discovered the structure of the atom in May 1911. According to Freeman Dyson, ‘the clear evidence for an atomic nucleus was long ignored by Rutherford’s contemporaries’. His book *Radioactive Substances and Their Radiations*, in which the structure of the atom is for the first time clearly spelt out, was reviewed in *Nature* in 1913 by Lord Rayleigh, ‘surely as broad-minded and versatile a physicist as one could find’; the review did not even mention the subject of atomic structure.¹⁰⁹

The individual researcher is less independent these days. When Rutherford discovered the nucleus of the atom, he published it in a paper with just a single author: himself. By contrast, the two 2012 papers announcing the discovery of the Higgs particle had roughly a thousand authors each. This is a recognisable trend. Many kinds of scientific research, especially those that rely on machines that are expensive to buy and expensive to run, require small empires, in which getting large research grants is the name of the game, bringing power and prestige to those at the top of the pyramid. Rutherford made his discovery with the simplest equipment: he had wanted a big, water-cooled magnet, but is said to have ‘dropped it like a hot cake’ when he learnt its cost.¹¹⁰ Gone are the days when good research was regularly done with the aid of one’s wits and a

pencil and paper – and where, partly because of this, people were given more freedom to pursue interesting ideas of their own that might or might not lead to a breakthrough. Researchers must now show ahead of time the value and likely outcome of their research, an approach which is adverse to the life of the mind. As we saw, tripling your budget increases your chance of publication. The whole process of research is now so predicted and monitored that originality, imagination and serendipity – all essential ingredients in new scientific work – cannot thrive. If we were to stop trying to micro-control the process, some research, it is true, would go slowly nowhere; but if we don't free up the process from such control, we'll all be going nowhere fast.

After analysing more than 65 million papers, patents and software products that span the period 1954–2014, the authors of a paper in *Nature* conclude that:

Experimental and observational research on groups reveals that individuals in large groups ... generate fewer ideas, recall less learned information, reject external perspectives more often and tend to neutralize each other's viewpoints ... Small teams disrupt science and technology by exploring and amplifying promising ideas from older and less popular work.^{[111](#)}

That last phrase resonates particularly with me, since I have found enormous riches in now neglected works produced in a freer and more untrammelled intellectual climate that is not actually so very long – less than a century – ago. Historically, many steps forward – the Renaissance is an obvious example – were taken by rediscovering what certain original scholars saw we had lost sight of, but cast in a new form.

The authors of the *Nature* paper draw attention to the attractions of large research budgets. Scientists, they say, 'like to portray science in a positive light, emphasizing benefits and minimizing negatives. While understandable, the evidence is that science has slowed enormously per dollar or hour spent'. They point out that there has been a falling away of Nobel Prizes awarded in physics for recent work since 1990: 'The 1990s and 2000s have the dubious distinction of being the decades over which the Nobel Committee has most strongly preferred to skip, and instead award prizes for earlier work. Given that the 1980s and 1970s themselves don't

look so good, that's bad news for physics.'¹¹² They found similar results in Nobels for chemistry, and physiology (which includes medicine).

Here we see the results of the left hemisphere mindset at work: profit must be maximised by making sure that everyone is maximally efficient. Thus, through the pursuit of efficiency, effectiveness is destroyed.

Competition for places in the steep hierarchies of the science establishment is fierce, and those who want to get on have no incentive to question, to step out of line in any way, or to think for themselves. There develops what Smolin refers to as a 'swaggering' and 'arrogant' style, which is used to intimidate and discourage anyone who questions the conventional wisdom.¹¹³ Yet

science requires a delicate balance between conformity and variety ... if science is to move forward, the scientific community must support a variety of approaches to any one problem ... While few would disagree with the rhetoric of diverse views, it is being practised less and less ...¹¹⁴

The point about diversity of approach is not primarily about giving everyone a fair deal. It is not about individuals at all. It is about the viability of the *communal* business of science.

Although objectivity, in the sense of a fair consideration of all possibilities, is a fine aim, objectivity in the sense of adopting a viewpoint that makes no presuppositions is, as I have suggested, intrinsically impossible to achieve. Fortunately science does not require objectivity. 'One of the strengths of science', writes historian of science David Hull, 'is that it does not require that scientists are unbiased, only that different scientists have different biases.'¹¹⁵ There's wisdom in that: but for that to be the case, one needs science to be open to as many different points of view as possible.

Smolin continues:

There are fewer corners where a creative person can hide, secure in some kind of academic job, and pursue risky and original ideas ... Whereas university faculties have stopped growing, there has been a marked increase in the number and power of administrators. Thus,

in hiring, there is less reliance on the judgment of individual professors and more on statistical measures of achievement, such as funding and citation levels. This also makes it harder for young scientists to buck the mainstream and devote themselves to the invention of new research programs ... It often seems as though achievements requiring nothing more than cleverness and hard work are valued more highly than probing thought or imagination. Intellectual fads are far too important, and people who ignore them have dicey academic careers ... universities don't function well as vehicles for innovation, even when nothing more is at stake than modernising a curriculum that is eight decades behind the science ... good ideas are not taken seriously enough when they come from people of low status in the academic world; conversely, the ideas of high status people are often taken too seriously.¹¹⁶

A significant point here is that even if professors were not, as they now are, constrained by having to make decisions on the basis of indices, etc, they are now increasingly likely both to have done too much line-toeing during their formative years, and to want to retain their position, its emolument, and the chance of public recognition, by continuing to conform to whatever 'standards' administrators impose. Modern science, writes Peter Lawrence,

particularly biomedicine, is being damaged by attempts to measure the quantity and quality of research ... The measures seemed, at first rather harmless, but, like cuckoos in a nest, they have grown into monsters that threaten science itself. Already, they have produced an 'audit society'¹¹⁷ in which scientists aim, and indeed are forced, to put meeting the measures above trying to understand nature and disease ... trying to meet the measures involves changing research strategy: risks should not be taken as this can mean long periods trying out new things, good for the originality of research but bad if a grant has to be renewed.¹¹⁸

This development is also a good example of how an attempt to enforce 'objectivity', in order to increase fairness and diversity, a left hemisphere

misapprehension, leads to a skewed situation in which diversity is minimised and true fairness – that the excellent should flourish – is travestied, with the result that neither academe as a whole, nor the creative individual, is better off. Mediocrity results, and science, and therefore all of us, are the poorer for it.

Even those who toe the line sufficiently to remain in a team that is successful in this game of snakes and ladders will find that the need to maximise publications causes juniors to be treated more like technicians than encouraged to become the scientists of the future. Yet this is the most important time for them to be untrammelled. Original work in a field like physics was often in the past achieved by those least worn down by the pressures of conformity and most open to fresh thinking: the young. Newton was 23 when he developed his theory of gravity. Einstein was 25 when he discovered the theory of relativity; Pauli was 25 when he announced his exclusion principle; Heisenberg was 26 when he presented his uncertainty principle; Dirac was 26 when he discovered his relativistic equation; Bohr was 28 when he developed his atomic theory; De Broglie was 28 when he made his breakthrough in wave mechanics; and even Schwinger and Feynman found the renormalisation solution before the age of 30, despite the interruption of World War II.¹¹⁹ This is not because young people are cleverer, and it cannot be that they know more: it is surely that their minds are more open than those of their seniors.

Research shows that there is a surge in original publication in an area once a leading figure dies, and that real advances are obstructed by a prestigious establishment with no reason to be prised away from the view it has always held.¹²⁰ ‘A new scientific truth’, said Max Planck, the originator of quantum theory, ‘does not triumph by convincing its opponents and making them see the light, but rather because its opponents eventually die, and a new generation grows up that is familiar with it.’¹²¹

The celebrated neurologist and brain researcher Norman Geschwind saw a larger picture that disturbed him. ‘There is a widely held supposition that one’s scientific peers are honest, well informed, not swayed by prejudices, and *open to imaginative adventures into the unknown*’. He calls this supposition ‘a utopian faith in scientific advance’, one that is contradicted by ‘many occurrences which demonstrate that although science has replaced religion in the minds of many educated people, the unquestioning belief in the virtues of scientists may be as misinformed as

the older faith that the clergy were always the true repository of spiritual values.’ He refers to ‘the many instances of deliberate falsification of data’, and mentions (writing in 1984) that ‘within the last several years’ researchers at the medical schools of Harvard, Yale, Cornell, and Boston University had been dismissed as a result of inventing or plagiarising data.’¹²²

What I would emphasise here is not that this less than sweet-smelling hierarchy is merely unpleasant, self-serving and corrupt – most hierarchies are – but how much it is *not* imaginatively open. And Geschwind notices a discrepancy that I also find troubling. ‘There is a vehement reaction’, he writes, ‘against what are construed to be anti- or pseudo-scientific activities ... yet instances of scientific fakery activity are typically regarded as random aberrations which lead to unfavourable publicity.’ This despite the fact that ‘examples of scientific chicanery have been so common that one can hardly neglect them’.¹²³

What makes Geschwind’s account so pertinent here is that his observations are set against the backdrop of a setback in neurology occasioned by the almost total suppression, for about 60 years, of vitally important information about the effect of disconnecting the two brain hemispheres – because it didn’t happen to fit the prevailing theory. It is often thought that we started to learn about hemisphere disconnection only with the first split-brain operations in the 1960s. However, there are brilliant, detailed and vivid accounts of the effects of stroke affecting the corpus callosum going back to Hugo Karl Liepmann in 1900,¹²⁴ and Kurt Goldstein in 1908,¹²⁵ the latter being reported and discussed in *Brain*, Britain’s most prestigious neurology journal of the period, in 1914 by Kinnier Wilson.¹²⁶ ‘The remarkable fact is, writes Geschwind,

that despite these superb descriptions of the clinical picture of callosal disconnection by master observers, and the confirmation of the location of the damage at post-mortem examination, almost every bit of this fundamental knowledge disappeared from the neurological literature ... Even more striking than the neglect of this original knowledge concerning the functions of the corpus callosum and its disorders was the appearance in the literature of incorrect

descriptions or bold statements that nothing was known about the callosum and its functions.'

To Geschwind's amusement, Walter Dandy, a pioneering neurosurgeon at Johns Hopkins, 'went so far as to state that, on the basis of his own experience, he could dismiss all the fantastic claims which had been made for the functions of the great cerebral commissure.'¹²⁷

Science has two opposing thrusts, although they are often imagined to be aligned. It cannot avoid operating under a paradigm, because, without such a paradigm, its findings could not cohere. This is not a criticism but an inevitability. Not inevitable, however, though highly likely for a range of reasons, is that in practice this leads to science being resistant to imaginative insights. For almost all scientists, almost all of the time, the business of science is the solving of problems which are framed and interpreted solely within the prevailing paradigm. This is what Thomas Kuhn refers to as 'normal science'. It leads to further establishment of findings within the paradigm, but it militates against those great insights that change the direction of scientific history, despite this being widely believed to be precisely what science is about. 'Few people who are not actually practitioners of a mature science', writes Kuhn in his landmark work, *The Structure of Scientific Revolutions*,

realise how much mop-up work of this sort a paradigm leaves to be done or quite how fascinating such work can prove in the execution. And these points need to be understood. Mopping-up operations are what engage most scientists throughout their careers. They constitute what I am here calling normal science. Closely examined, whether historically or in the contemporary laboratory, that enterprise seems an attempt to force nature into the preformed and relatively inflexible box that the paradigm supplies. No part of the aim of normal science is to call forth new sorts of phenomena; indeed those that will not fit the box are often not seen at all. Nor do scientists normally aim to invent new theories, and they are often intolerant of those invented by others. Instead, normal-scientific research is directed to the articulation of those phenomena and theories that the paradigm already supplies.¹²⁸

This can become a self-referential, self-validating procedure, which is all the more devastating because true science is neither of those things.

The attempt to save the paradigm is a perfectly reasonable one, but only if it is balanced by an equal willingness to be aware of its limitations in the face of new evidence. Too little adherence to the paradigm and the wheels of science spin without purchase; too great adherence and they are stuck. In either case no progress is made. It is much more comfortable not to raise new ideas, because they will be met with opposition or ridicule, and most people are petrified of stepping out of line, not least because their career prospects depend on toeing it. A recent article entitled ‘A call for an open, informed study of all aspects of consciousness’, signed by 100 scientists, many of them holding chairs at prestigious universities, made the point that research into consciousness is hampered by blind adherence to an unproven dogma that consciousness must arise only from material causes.¹²⁹ Our minds are so constructed that we actually don’t even see the discrepancies that our theory involves until the deviations are so gross we have no alternative.¹³⁰

The certainty that what one was taught to believe must be right afflicts even the best scientists. It meant that Tycho Brahe could never accept Copernicus’s discovery of the circulation of the earth round the sun, and that Justus von Liebig, the founder of organic chemistry, could not accept the germ theory of disease put forward by Louis Pasteur and Robert Koch. In the words of Bernard Barber, ‘because of their substantive conceptions and theories, scientists sometimes miss discoveries that are literally right before their eyes.’¹³¹

Stepping out of line is a very serious business that takes moral courage: whether right or wrong, you will be vilified by some and may lose your livelihood. In case you think that might be an overstatement, I can tell you that many scientists say in private that they believe in purpose in nature – with no necessary implication of a designer God – but cannot say so in public for fear of losing their job. Purpose in nature is not the same as Intelligent Design, but Intelligent Design is of course anathema to mainstream science.

Take the case of the distinguished palaeontologist Dr Günter Bechly. Until 2016 he was Curator for Amber and Fossil Insects in the Department of Palaeontology at the State Museum of Natural History in Stuttgart, a highly prestigious post. According to his website not only has he published

over 160 peer-reviewed scientific papers, but he has described, or co-described, 172 new species, and numerous new genera and higher taxa, including three new orders of insect; no less than 11 taxa have been actually named after him. So hardly an outsider to scientific research. He put on one of the largest, if not the largest of, celebrations in Germany of Darwin's work in the bicentenary year of Darwin's birth, 2009: the exhibition, which attracted around 100,000 visitors, and which was designed to refute Intelligent Design theory, was awarded a coveted prize. However, he made the mistake, during the Darwin celebrations, of thinking that he really ought to read the pro-design books that he had put up to be dismissed. When he did, he found to his surprise that they had been misrepresented. They were much more sophisticated than he had been led to believe. He then had a crisis of conscience. Having been a lifelong atheist, and a follower of Richard Dawkins,¹³² in 2015 he was foolish enough – or brave enough – to express open support for Intelligent Design: 'I did not change my views in *spite* of being a scientist but *because* of it, based on a careful and critical evaluation of empirical data and rational arguments, following the evidence wherever it leads', Bechly says.¹³³ He was immediately forced to leave his post; and English-language Wikipedia, until then, understandably, considering him a considerable scientist meriting a Wikipedia page, removed his entry. He has become effectively a non-person.

Let me be clear: I am not in a position to judge whether Bechly is right. I do not espouse Intelligent Design as I understand it (though I suspect that there is a broad range of views gathered under that rubric), for reasons that will become more obvious to readers of Part III of this book: but I also do not dismiss those who hold to it, since I simply do not know enough to be dogmatic. My point is that, in a properly functioning scientific establishment, the expression of such views should at least be entertained, if not welcomed, and certainly not silenced. If the argument has been already conclusively decided against teleology, it should not prove difficult to counter such views, and in doing so to enlighten those who really want to know the truth. But it has not. Such beliefs are widespread among scientists. Over 1,000 scientists, including those holding academic posts at or holding doctoral degrees from universities including the likes of Oxford, Cambridge, Harvard, Yale, Stanford, Princeton, Cornell and MIT, have risked jeopardising their careers and livelihoods by signing a statement that 'we are skeptical of claims for the ability of random mutation and natural

selection to account for the complexity of life. Careful examination of the evidence for Darwinian theory should be encouraged.’ According to Philip Skell, a member of the United States National Academy of Sciences, and a former Evan Pugh Professor (an award for exceptional achievement) at Pennsylvania State University, ‘scientific journals now document many scientific problems and criticisms of evolutionary theory and students need to know about these as well ... Many of the scientific criticisms of which I speak are well known by scientists in various disciplines, including the disciplines of chemistry and biochemistry, in which I have done my work.’¹³⁴ The irony is that Darwin, in his modesty, would have been all in favour of taking such views seriously. The neo-Darwinists, it would seem, are less enthusiastic about doing science.

Then there is the discrepancy in status that turns established senior figures against their perceived inferiors. Though, in the best case, their very status might free them to think more imaginatively, more established figures, of higher status, have had more reinforcement of their preconceptions, and have more to lose by embracing new ideas. Geschwind remarked that ‘it has become increasingly clear that scientists, even when honest, may engage in destructive competition and backbiting, often at the expense of vulnerable and junior people.’¹³⁵ The great botanist Karl von Nägeli patronised and dismissed the humble monk Gregor Mendel, whose experiments laid the foundations of modern genetics. And there is a prejudice against outsiders, who have the advantage of not starting with the same preconceptions. Helmholtz’s crucially important discoveries in physics were dismissed because he was a medical doctor and philosopher by training; equally Pasteur’s and Magendie’s medical discoveries were dismissed because they were not physicians.

There is a tendency for many scientists to take an uncritically contemptuous, and at times, frankly, self-righteous attitude, to whatever might challenge the mainstream of conventional thinking. This is not only unattractive, but unscientific. We are rightly scandalised when the clergy put preservation of the comfortable edifice of the Church ahead of abiding by Christian principles in practice. Why are we tolerant of scientists who, *mutatis mutandis*, do the same thing? My claim is certainly not that there is something wrong with science, but that the contemporary science establishment is *not scientific enough*. That would require keeping an open mind and taking seriously, as does physics, non-mechanistic models.

Seriously enough to deal with them fairly. What we have here amounts to a groundless prejudice. As a result we are both missing great potential discoveries and stultifying the human mind. ‘Science means, first of all, a certain dispassionate method’, wrote William James:

To suppose that it means a certain set of results that one should pin one’s faith upon and hug forever is sadly to mistake its genius, and degrades the scientific body to the status of a sect ... Although in its essence science only stands for a method and for no fixed belief, yet as habitually taken, both by its votaries and outsiders, it is identified with a certain fixed belief, – the belief that the hidden order of nature is mechanical exclusively, and that non-mechanical categories are irrational ways of conceiving and explaining even such things as human life.^{[136](#)}

The left hemisphere mindset likes conformity, seeks power, and has difficulty understanding the non-mechanical. I suspect it is operant here. It also tends, as we know only too well, to denial.

CONCLUSION

Science is a project that, when carried out in a spirit of humility, is exciting, and potentially beautiful and good, even if not necessarily always in possession of the truth. It can offer no answers that are not framed by a context – because truths are always limited by context. Earlier I quoted Whitehead to the effect that the question to be asked of scientific claims is under what circumstances they are true and under what circumstances they are false. This question often remains unasked. The left hemisphere tendency, unlike that of the right, is to take things out of context: yet it is awareness of context that gives us necessary awareness of the fallibility of a dogma. In philosophy there is a position known as ‘pessimistic meta-induction’, which views the history of science as the history of perennially mistaken ideas. While this does seem a very one-sided way of looking at things, it reminds us that today’s fact is tomorrow’s artefact.

The theories of Einstein could be put to the test, though they cannot be proved, and may need to be modified in the light of further information. Neither Darwin nor Freud produced hypotheses that can be ‘disproved’ by any conceivable experiment. It is a myth that science depends on such a stipulation. Even single findings, never mind whole theories, may prove very hard to falsify. Falsification is a complex business, characterised by incremental judgments, not by unambiguous precision. It is a matter of testing new ideas out against the rest of our experience of the world, in Darwin’s case the natural world, or, in Freud’s case, the human inner world – a matter of whether they open our eyes to something, so that after that we can hardly *ignore* the truth it constantly unconceals. That is the only possible test of great truths. As Richard Feynman said during his Nobel Prize acceptance speech in 1965: ‘A very great deal more truth can become known than can be proven.’ And, I might add, a very great deal more falsehood can become known than can be disproved.

Willard Quine and Pierre Duhem pointed out that things are not propitious for those who demand proof, since not only can a finding never be proved, as is widely accepted, but it cannot be finally *disproved*, either. This is because each finding is embedded in a host of assumptions, and it may be one of those assumptions that is at fault, not the finding. We simply

cannot avoid the exercise, however hard we try, of (informed) personal judgment. That doesn't, of course, entail that every judgment will be equally valid; just that the issue isn't subject to proof.

Interestingly the word 'proof', which now means a way of showing that something is the case beyond doubt, used to mean a trial run, as in a proof of a printed article, or putting something to the proof, tasting it, trying it out (cf French *éprouver*). It was a trial, in the sense of trying something out (for that word, too, is slippery) rather than a trial in the sense of a legal process leading to a judgment of fact. When one is 'trying' something nowadays, is one opening oneself to the experience, without which one will never know? Or 'trying' it in the sense of a court of law, whereby it will be finally found, in the abstract, to be right or wrong? The word 'experience' comes from the Latin *experientia*, from *experiri*, meaning to 'try out'. And that comes from the same Proto-Indo-European root *per-* which underlies our word 'peril' and the German word for danger, *Gefahr*. Experience is an inherently uncertain business that carries risk – a risk without which one can learn nothing. Such is our world, and such are the terms of our existence. And such was Blake's perception, when, referring to his own birth, he wrote: 'My mother groaned, my father wept, / Into the *dangerous* world I leapt.'¹³⁷

The right hemisphere view of proof derives its value from the context, and so can never be absolute, regnant for all regions of space and time, and never single or immune from evolution. The idea of truth as independent of us, immutable and certain, is a relatively recent invention. In this chapter I have argued that we need to regain the strengths of the right hemisphere's 'antifragile' idea of truth and proof, and lose the weaknesses of the brittle, 'fragile' left hemisphere idea of each.¹³⁸

Some people think that science must be a principally left hemisphere business. I'd caution that, like absolutely everything else, it has its left hemisphere and its right hemisphere aspects. And, like everything else, science profits from balance and harmony between them. Some kinds of scientific thought, especially the drive to see the overall shape, to draw together disparate findings, to make connexions, to achieve imaginative insight, to evolve, or to modify a hypothesis, to observe things as near as possible as they are (empiricism), and to see whole systems that can't be reduced to linear connexions, are likely to be more right hemisphere-dependent; the drive to make fine distinctions, to investigate localised areas or functions, to preserve the theoretical paradigm at all costs, to achieve

certainty, to see the world in terms of things that are cause and effect to other things, in predictable, linear fashion – all this is more likely to express the contribution of the left hemisphere. Both are essential: though here as always, it is the right hemisphere's role that needs to predominate, taking under its aegis the contribution of the left hemisphere. There needs to be a balance between opening up the flow of thought to possibility and closing it down towards an always provisional certainty. Certainty is always a matter of degree; about that I am as certain as it is humanly possible to be.

As the left hemisphere mode of construing the world predominates, however, things become unbalanced. Science is reconceived as a fundamentalist movement: prone to self-righteousness, closed to unfamiliar ideas, defensive, complacent, open to corruption and risking a lifeless failure of imagination. If you are like me, you will admire science for what it can do at its imaginative, mind-expanding and exciting best, but draw the line at what it never could – namely provide us with dependable, or ultimate, truths.

Seeing that I rely heavily on science, am I not vulnerable to my own arguments? To an extent, yes, of course. But only, I believe, to a limited extent.

There are two ways in which I might be. One is 'essential', and concerns the truth available to science; the other is 'accidental', and is about the validity of the particular evidence on which I rely.

As far as the first is concerned, I don't claim any more than science can legitimately claim – but that is a very great deal. I caused some confusion at the end of *The Master and his Emissary* by suggesting that, while I thought it unlikely I would be wholly right about hemisphere differences, I thought it unlikely I was wholly wrong; and that even in the improbable event that there was *nothing* in my hypothesis about the two hemispheres, and it turned out to be 'just' a metaphor, I would be content, since 'I have a high regard for metaphor. It is how we come to understand the world.' Some literal-minded individuals have interpreted this as meaning that I don't believe in the scientific validity of my own hypothesis. It will hardly surprise you to learn that I do. I wouldn't have spent a large chunk of my life on the scientific data and evaluating my hypothesis against it if I didn't. It's just that I also understand that metaphor is not opposed to truth, but the basis of all meaning, including – and even particularly, as philosophers George Lakoff and Mark Johnson claim – in science and philosophy.

As far as the second issue goes, the dependability of the science research on which I rely, no-one can avoid this nagging question. Yet science would be brought to a standstill by too great an insistence on dependability. The best security comes from drawing on as large, as broad-ranging, and as representative a base of evidence as one can. Wherever possible – and clearly that can't always be the case – one should try to ensure that assumptions are based on studies of different types, employing more than one method of approach (thus minimising the chances that the findings are all vulnerable to the distortions inherent in one methodology); on studies coming from more than one era (thus minimising the chances that the findings are influenced by fashion); in the case of a neuroscience hypothesis, not solely on the results of scanning studies (which are more prone to distortion and problems of interpretation than any other methodology); and, in the case of a human neuroscience hypothesis, on findings that are consonant, if at all possible, with those in animals, where relevant. This is a counsel of perfection, but I have tried as far as possible to follow these principles.¹³⁹ And I have been very lucky: I have had what is these days, alas, the luxury of not being forced to crystallise my thinking prematurely, and of being able to gather evidence on a large scale over long periods of solitary time.

I also think it more likely that one is on the right track if one's findings precipitate a coherent and integrated *Gestalt*. On this last point, it seems to me one of the strengths of the hemisphere hypothesis that it makes sense not in a piecemeal way, but as a whole synthetic project, proposing coherent experiential worlds, not just a randomly assorted set of findings. The test will be how well it answers to, and helps make sense of, the further findings we make over time and our lived experience. A working hypothesis, in other words. And, as von Neumann suggests, we can't know more in the way of scientific truth than that our hypothesis works. The hemisphere hypothesis is inevitably provisional, and with luck my provisional thoughts may be useful to others.

Nonetheless, what I am engaged in, here and in the next few chapters, may seem paradoxical. I am, as you know, not as troubled by that as others may be: it may be a sign that I am on the right path. But it is odd that it falls to someone whose argument depends on reason and scientific evidence to be the one to point out the limitations in both. However, my aim is to make both of these paths to certain kinds of truth the stronger, by clearing them of

false conceptions which only leave them open to misunderstanding, and to some extent, therefore, to the erosion of the respect which is their proper due. And to set them in a proper relationship, and harmony, with other possible paths to truth.

An attempt to restore balance is a thankless task. My reward for this may be that I will be seen by some as attacking science or reason; and be seen as offering comfort to those with whom I deeply disagree in their disregard and disrespect for the values that science and reason at their best uphold. By others I will be seen as a reductionist for placing as much emphasis as I do on the value of science and reason in helping us understand our all too human predicament. But those who insist on seeing what I say in a perverse light I cannot help: they won't want their prejudices to be disturbed.

Let me never be adduced in evidence against science. Science is, or should be, a source of wonder that opens out our understanding of the world and gives us one of the touchstones on the path towards truth. Just because science cannot answer all our questions does not mean that it is not the very best way to answer some of them, and a helpful contributor to answering many more. And that there is corrupt practice in science does not make it different from any other human enterprise. Anyone that is misguided enough to reject science must have a very limited imagination, as well as being blind to many beautiful truths, and will make many errors. But the same is true of anyone who accepts only science. For it can also become a tool that banishes wonder, stunts imagination and narrows down understanding, before closing the mind altogether. That is, however, what bad science does: it is not intrinsic to science. To see the limits of science empowers it; to see no limits to it strikes at the very heart of the enterprise.

I believe some of the political difficulties we are now experiencing in the Western world come from a lack of balance, in which wilful blindness to the problems in one's own position eventually causes an ignorant and extreme reaction, when those who are at some level all too aware of what is being ignored and denied can finally contain themselves no longer. Those liberal intellectuals who had their doubts about the Western liberal intellectual consensus of the last few decades were stigmatised for not having unlimited enthusiasm. Those who criticised the consensus liberal position for its excessive one-sidedness, before it was too late, were seen as enemies: they were in fact friends. 'Plato is my friend, but a greater friend

is Truth', as Aristotle is said to have remarked; falsely, as it happens – but such is life. [140](#)

REASON & TRUTH

REASON'S CLAIMS ON TRUTH

Reason is the special embodiment in us of the disciplined counter-agency which saves the world.

—*Alfred North Whitehead*¹

The pride with which some artists announce that they cannot think logically reflects an attitude complementary to, and as dangerous as, the view that one needs only to be able to think logically.

—*Jan Zwicky*²

It is equally excessive to shut reason out and to let nothing else in.

—*Blaise Pascal*³

IN THIS CHAPTER, AND THE NEXT, I EXAMINE WHAT THE HEMISPHERES CAN tell us about the use of reason as a guide to ultimate truth.

Heidegger said: ‘We may venture the step back out of philosophy into the thinking of Being as soon as we have grown familiar with the provenance of thinking.’⁴ What, then, is the ‘provenance’ of thinking? To question the provenance of something is to ask where it comes from, and whether we should take its claims at face value – as in the ‘provenance’ of a drawing attributed to Leonardo.

So what is reason?

Reason, wrote Whitehead, is ‘the discipline of shrewdness’. And he went on: ‘Reason which is speculative questions the methods, refusing to let them rest.’⁵ It is, in other words, a critical discipline, more than a creative faculty, questioning our ways of thinking and keeping us from complacency, its first target being our ‘methods’ – which include itself. Arguably it is the widespread philosophical failure of science to question its methods that has led to the problem of scientism.

And what are reason’s methods?

Reason suggests a linear way of thinking, seeking chains of causation, which makes sense only in a limited environment. Its mode of operation is local, one bit at a time.

Reason suggests a global, holistic understanding, which makes sense only in the round. It is a seamless apprehension of the world.

Yes, you read that correctly. Reason means different things – has in particular two distinct meanings. In our world, one is becoming predatory, the other disappearing like a hunted animal.

The first is what a calculating machine, otherwise known as a computer, can do. At least it can be made to look as if it does by human beings who put in the rules for linear procedures, give it material to work on and interpret the results. In its increasingly pervasive interactions with us, the machine inevitably imposes on us what a clever urban geek put into it last year, as though this were the most intelligent way of conducting human life. It doesn’t know that in humans this is a very strange way of behaving, because there is no tempering of rule-following with reason – of the second kind. That can be offered only by a living, fully feeling, embodied being, since it draws on *value*, and on the vast, complex store of human experience, reflecting an understanding of how particular cases always differ by virtue of context.

In this way the first mode of reason replicates in us something like a way of looking at the world normally found in mental illness. A kind of (itself irrational) rationalising and a neglect of reasonableness are, as we have seen, striking characteristics of both schizophrenia and autism, which tend toward an unbalanced, rigid, disembodied, procedural type of mentation, lacking in normal emotional intelligence.

The second is what gives integration to our world. It sees the big picture and sees that the details are inevitably subordinate to that bigger picture.

Whitehead saw that what had gone wrong in the Dark Ages was the loss of this integrating faculty:

It is not merely that in the earlier times the men knew less. They were intrinsically less able in moving about among general ideas. They failed to discriminate between minor peculiarities of details and the major notions. The power of going for the penetrating idea, even if it has not yet been worked into any methodology, is what constitutes the progressive force of Reason. The great Greeks had this knack to an uncanny degree. The men of the thirteenth century had it. The men of the tenth century lacked it ...⁶

And, I would claim, we largely lack it now once more.

English has, for better or worse, become the *lingua franca* of the modern world. The distinction I am making between two kinds of reason is disguised in English by its using the same word for two very different phenomena. In other languages, it is not necessarily so. In German there is a distinction between *Verstand* and *Vernunft*, in Latin between *ratio* and *intellectus*, in Greek between *dianoia* and *nous*: in the first of each case, what one might call, in the absence of anything better, *rationality*, a *linear* process; in the second, *reason*, an understanding in the *round*. I suggest that these two versions reflect the typical mode of operation, and exemplify the characteristics of, the left and right hemispheres, respectively. The first is rigid, aims for certainty, tends to 'either/or' thinking, is abstract and generalised, ignores context and aims to free itself from all that is embodied, in order to gain what it conceives to be eternal truths. The second is deeper and richer, more flexible and tentative, more modest, aware of the impossibility of certainty, open to polyvalent meaning, respecting context and embodiment, and holding that while rational processing is important, it needs to be combined with other ways of intelligently understanding the world.

The philosopher Ernest Gellner referred to

the 'mechanistic' insistence on impersonal, structural explanations ... It was Kant's merit to see that this compulsion is in us, not in

things. It was Weber's to see that it is historically a *specific kind of mind*, not human mind as such, which is subject to this compulsion.⁷

Much philosophical reasoning is of the first kind – for two thousand years in the West, between Plato and Kant, it was more or less exclusively so. Elsewhere in the world, and at other times in the West, this kind of thinking, the kind associated more with the left hemisphere than the right, has been considered of only limited use, and a potential source of misunderstanding when given too much credence. According to this point of view, not to temper it with other modes of understanding would itself be contrary to reason. The problem is, however, that once one is inside the rationalist bubble, one can no longer see any need to break out of it, let alone any way of doing so. As Stanley Fish put it, 'does reason [ie, rationality] know what it is missing?'⁸

Rationality is exclusive: reason is inclusive, balancing rationality with intuition, emotion and imagination. Emotion is not, as some Enlightenment philosophers thought, necessarily an impediment to reason, but an essential component of it. If you need a demonstration, the patient 'Elliot' reported by Antonio Damasio (referred to in Chapter 7) will serve. In his case, as a result of a tumour, 'a large component of the right frontal cortices was not functionally viable.'⁹ No longer able to intuit the value or emotional meaning of life situations, he was reduced to trying to compute rationally, as from first principles, in every case, and his life became insupportable. Not only did he take for ever to decide what to think or to do, but he reached, for an intelligent man, some very foolish conclusions.

And it is one of the messages of this book that imagination is not an impediment, but, on the contrary, a necessity for true knowledge of the world, for true understanding, and for that neglected goal of human life, wisdom.

Thus there is such a thing as reasoned truth, just as there is such a thing as scientific truth; but both are inseparable from the humanity that gives rise to them, both are provisional and uncertain. As with science, the vice is that of trying to avoid (what we call) the subjective by asserting (what we call) the objective. This presupposes that there is an 'us and them' about the world: something 'in here', trying to copy as well as it can something 'out there', and usually not doing it well. The one that is thought (on unclear

grounds) to do it best is said to be objective, and that in turn is taken to be the truth.

But it is the left hemisphere's process of apprehending the world that gives rise to the very idea of the 'subjective' and 'objective' – a false dichotomy. As I suggested in Part I, there is, rather, as disclosed by the mode of the right hemisphere, a 'betweenness' to reality; a world that comes into being for us, which, to paraphrase Wordsworth, we half perceive and half create. That doesn't mean that half is objective and half subjective, or half real and half a fantasy. It means that the coming into being of the world is, wholly and simply, an encounter, to which inevitably both parties contribute, and in which both parties are real: a something that is given *in our very experience of it*. That something is not an image, not a shadow, not a *representation* of something else. In as far as it falls short, it's because this something is only ever *partially* given – because inevitably partially *hidden*. It is like the Japanese Zen garden, Ryōan-ji, in which, from any one viewpoint, there is always at least one of the 15 stones that cannot be seen. Note that this does not imply there is something we *never* see; just that there does not exist a viewpoint from which everything can be seen at once.

To clarify, I am not saying that all I can know is a simulacrum, the relationship of which to a reality that I can never know I also can never know. I am saying that what I know is real enough, but it is only what I am able to see from where I am: a tiny portion of the whole. This differentiates a particular state (one that applies to each one of us, but somewhat differently) from the supposed deficiencies of a general state (one that applies to us all similarly). Not partially real, but really partial – or, better, wholly real and wholly partial. Not 'as is a landscape to a blind man's eye', but as is the living presence of the landscape of the Wye valley to William Wordsworth on 13 July 1798. And what that also hints at is the awesome property of great art: that when he wrote those lines he was able momentarily to transcend those individual limitations, and thereby pass on to us, his readers, the gift of seeing, for a while, what he saw.

What we see is real enough. It is not like the relationship between a child's drawing of his mother and the mother he loves, which the drawing represents; it's like the relationship between what the child knows of love, and what, if she has lived life to the full, the mother knows of love. As Whitehead puts it: 'We must reject the distinction between nature as it

really is and experiences of it which are purely psychological. Our experiences of the apparent world are nature itself.’¹⁰

It is true that we all have different experiences, but they share very much common ground. There is another ‘betweenness’, which links us to one another in intersubjectivity. Thus each individual consciousness is not fused with, but neither is it wholly separate from, that of others; nor is the world wholly separate from each consciousness. It is because of this that we are enabled to reach a balanced, rich understanding of the world, not an idiosyncratically meagre one. And for this reason it is vital that philosophy takes place in the *second person*.¹¹ This is how I believe and hope I am addressing myself to the reader. Mind you, it was why Plato thought philosophy could not be written down at all. It was always a reciprocity of minds. ‘Dealing with subjective phenomena is not the same as dealing with purely private experiences, as is often assumed’, write Varela and Shear. ‘The subjective is intrinsically open to intersubjective validation (second person interactivity)’.¹² The attempt to speak in the third person only has a surprising amount in common with the attempt to speak in the first person only. Equally there is no betweenness; there is a suspicion of grandiosity about either.

‘Bias for impartiality is as much a bias as is partisan prejudice, though it is a radically different quality of bias’, wrote John Dewey, and continued:

one can only see from a certain standpoint, but this fact does not make all standpoints of equal value. A standpoint which is nowhere in particular and from which things are not seen at a special angle is an absurdity. But one may have affection for [incline towards] a standpoint which gives a rich and ordered landscape rather than for one from which things are seen confusedly and meagrely.¹³

Dewey is not maintaining here that one just sticks to whatever point of view one happens to have. This is no charter for every partisan; on the contrary. To find the ‘richest’ view, the one that seems truest to the world as a whole, in the sense that it resonates with our experience in the richest way, the imaginative exercise of inhabiting a number of points of view is required. Seeing things from as many points of view as possible, so that we

don't see them 'meagrely', is not mere subjectivity. Nor is it falsely claimed objectivity: in different ways it is the opposite of each.

No '-ism' that is already *parti pris* can offer a 'rich and ordered landscape', because the mind that gives rise to it is closed, disregards the whole tapestry of reality in favour of just one strand, and inevitably needs to disparage those points of view it doesn't share. The rich view, by contrast, will draw from a number of standpoints and achieve a balanced synthesis.

The physicist Leo Szilard once announced to his friend Hans Bethe that he was thinking of keeping a diary:

'I don't intend to publish. I am merely going to record the facts for the information of God.'

'Don't you think God knows the facts?' Bethe asked.

'Yes', said Szilard. 'He knows the facts, but He does not know this version of the facts.'¹⁴

REASON BEYOND REASONING

Reasoning in the sense of rationality is a consistency tool, and nothing more. Its job is to tell us that if we hold *a* and *b*, and if we also believe that logical contradiction necessarily implies falsehood, then we must hold *c* as a consequence. It is an *intermediate* processor, albeit a very valuable one. It cannot ground itself, at the 'bottom' end, or give meaning to its outcome at the 'top' end. At the bottom end it must rely on axioms assumed on the basis that they are intuitively true (the word 'axiom' comes from the Greek word *axia*, meaning 'value' – in other words, reason is founded on what are in essence value judgments). Reason, like both science and, in a different way, morality, can bring a verdict into doubt only if it is grounded on something which is exempted from the doubting process. As Wittgenstein put it: 'the questions that we raise and our doubts depend on the fact that some propositions are exempt from doubt, are as it were like hinges on which those turn ... If I want the door to turn, the hinges must stay put.'¹⁵ Nor can it by itself give meaning to its results, at the 'top' end, but must rely on an intuitive grasp of a whole world in which alone they can be fully interpreted and understood.

Again, this is like the processing that a computer carries out. The computer neither understands the data that are put into it by a human consciousness at the start, nor understands the output, which equally requires a human consciousness, when the process is complete; but carries out an important task in the middle of this process. Even the rules by which logic operates, such as the 'law of non-contradiction' (that contradictory statements cannot both be true in the same sense at the same time) and 'the law of the excluded middle' (that for any proposition, either it, or its negation, must be true), have to be taken on the recommendation of intuition – and such intuition may be only partially reliable. These are choices, not laws: outside of courts there are no laws, only regularities. And these so-called laws of Aristotle were not intended as a description of how humans actually *do* think, but to suggest how a totally rational entity *might* think.

Pursuing logic will not in itself achieve understanding, which comes from living a thoughtful life. What the right hemisphere knows must be

already at least in part understood intuitively by another's mind for it to be *awakened* there. It cannot be *compelled* on that mind by a train of logic. This was a point pungently made by Samuel Johnson, replying to a 'pertinacious gentleman' who was unfortunate enough to say, 'I don't understand you, Sir'; to which Johnson replied, 'Sir, I have found you an argument; but I am not obliged to find you an understanding'.¹⁶

Even Plato, the founder of the Western dialectical tradition, thought argumentation was far from everything, as I mentioned in the Introduction. In his *Seventh Epistle*, he explained why he could not write a treatise on the nature of philosophy:

For [philosophy] does not admit of exposition like other branches of knowledge; but after much converse about the matter itself and a life lived together, suddenly a light, as it were, is kindled in one soul by a flame that leaps to it from another, and thereafter sustains itself.¹⁷

This sounds more like insight, robustly associated with the right hemisphere: the sudden dawning of a quasi-spiritual truth, in which reason, imagination and intuition together play their part in interpreting experience.

It is true that in the *Republic*, a dialogue some aspects of which are so problematic that it has been argued that it must have been intended ironically, Plato has Socrates tell us that 'we must follow the argument wherever, like a wind, it may lead us'.¹⁸ And in a similar spirit, in the *Sophist*, Plato has Theætetus say: 'I have to follow where the argument leads'.¹⁹ Though he might have wanted us to explore, for the sake of the argument, where it led, Plato would hardly have wanted us blindly to follow logic, since logic is only an 'unpacking' of what is hidden in our premisses. If our conclusions are absurd, we do well to go back and re-examine our premisses; just as, on any journey, if one finds oneself going astray, the intelligent course of action is not to persist along a path that is going nowhere, but to retrace one's steps.

Particularly when one initially has at least some reason for believing as one does, an awareness of one's own cognitive limitations might legitimately give rise to some measure of scepticism about arguments that attempt to undermine those beliefs.²⁰

So writes Princeton philosopher Thomas Kelly. This is one reason why one might want to qualify the idea of following an argument wherever it leads. Plato, it should be remembered, believed that philosophy was not just the following of procedures, but required moral qualities, including humility and a capacity for love. *Given these qualities*, reason may lead you closer to the truth; otherwise it may mislead.

But how is one to judge *when* one is going nowhere? Just because results are unexpected does not make them invalid: our cognitive faculties are one way of prising us away from cherished, but mistaken, beliefs. Just when we think we are lost, we may be about to stumble on hidden treasure. There is no single way to determine the matter. It can't be reasoned towards, because reason is exactly what we are trying to evaluate, and it can only carry on unpacking what it is given; intuition, though far from fool-proof, is probably a better guide, since it is based, at least, on all one's experience, not a single logical point, and intuition intuits the partial nature of its own understanding – a similar appreciation of its own shortcomings is harder for reason to come by.

The linear path is seductive to the left hemisphere's mindset in its directness and simplicity. But what seems like a virtue – that it does not change direction – reveals itself to be a vice. It has deep rhetorical power over Western minds, making it easier to believe not only that the direct approach is always the most rational, which it is not, and that reciprocal, contextual and feedback effects can be ignored, which they cannot, but that if something is good, twice as much of it will be twice as good, which is rarely the case, and that apparent opposites cannot coincide, which they can.

The linear path is responsible for the myth of progress. Philosophy progresses, if at all, by a process of circling one's 'object', revisiting it from different angles, often over many lifetimes. In the history of philosophy no more than the history of music should one imagine that worse only gives way to better over time. The important issues have been argued about for millennia without any firm conclusions being reached. That does not make the process pointless, of course, any more than the inevitably provisional and partial process of science renders science pointless: the journey, not the arrival, matters. It is one of Carse's infinite games. But this does suggest that we will not be getting anything from it which we can carry away, saying, 'this, then, is the truth'.

Rationality starts and finishes in intuition, which supports it like a pair of massive bookends. I agree with Jan Zwicky that ‘the ability to think analytically is as inalienably human as the capacities for love and grief ... It makes no more sense to attempt to eliminate it from human thought than it does to eliminate emotion, or desire.’²¹ But the value of reasoning itself is an intuition drawn from experience.

A note on my use of the term intuition here. Throughout I take intuition *not* to be an immediate perception of some unquestionable, timeless truths, as in the analytic tradition it has sometimes been taken to mean, but rather a matter of judgment based on the whole of experience, not just that little part of which we are conscious – deep, but not by any means infallible. Indeed, like all knowledge from whatever source, it is something always subject to correction or further refinement. A *Gestalt* is never absolute and final: its value is that it replaces one that accounts for less or takes less into account. ‘Philosophy advances’, writes Arran Gare, ‘as less perfect forms of philosophy are discarded and their valuable contents assimilated to more perfect forms. A philosophical system should be judged according to its coherence and comprehensiveness, and its capacity to surpass by including more limited philosophical stances.’²²

Moreover, rationality is dependent on intuition in a further way: we cannot justify rationality by reasoning, except by pointing to the fact that it often works, in the sense of delivering useful knowledge. Its worth, exactly like that of science, or of any philosophical approach, lies in that simple fact – that it ‘works’, in this sense – *where it does*. But how will we know where it *doesn’t* work, if we always assume, as in scientism, and ratiocentrism, that *where* it doesn’t, this can never count as evidence of the limits of the method, only of the limits of reality?

If reason sometimes gets between us and useful knowledge, why and when it does so cannot be simply reasoned towards, but again entails an appeal to the fruits of experience. So our commitment to reason is an intuitive one: our experience is that it is helpful to a certain degree in certain circumstances. Ignoring that nuance turns the matter unhelpfully black and white, to the impoverishment of our capacity to understand the world. As Whitehead put it, ‘the art of the speculative Reason consists quite as much in the transcendence of schemes as in their utilisation’.²³ We need to know when and how to use them to good effect, and yet know when to go beyond them. Reason should be our servant, never our master. Or as that

very reasonable man David Hume put it, 'reason is, and ought only to be the slave of the passions, and can never pretend to any other office than to serve and obey them.'²⁴

RATIOCENTRISM

As we saw in Chapter 8, the great advances of science and even mathematics are not typically made by reasoning, which is often filled in after the event, when the necessary accounting, the ‘paperwork’, must be seen to be done. Indeed such reasoning has been called ‘the endless paperwork of the mind’.²⁵

What philosophy absolutely depends on, and without which none of its enterprises is worth the paper it is scribbled on, is a *vision*. You can be as clever as you like at finding technical objections to the vision of another, but unless you have the courage to stand by one of your own, you are not a philosopher – just a logic-chopper. And a vision never results from following procedures. Philosophy, writes Waismann,

is not a matter of ‘clarifying thoughts’ nor of ‘the correct use of language’ nor of any other of these damned things ... At the heart of any philosophy worth the name is *vision*, and it is from there it springs and takes its visible shape ... Though to an outsider [the philosopher] appears to advance all sorts of arguments, this is not the decisive point. What is decisive is that he has seen things from a new angle of vision. Compared to that everything else is secondary. Arguments come only afterwards to lend support to what he has seen ... The substance of my remarks is that the conception of a whole philosophical view ... is never a matter of logical steps. A *Weltanschauung* like any of these or even a new approach like that of Wittgenstein is never ‘arrived at’, in particular it is not deduced, and once found it can neither be proved nor refuted by strictly logical reasoning ...²⁶

Philosophy is not, then, purely a matter of some abstract, procedural rationality. ‘Although professional philosophers nowadays are often highly skilled in matters of argument’, writes philosopher Bryan Magee, ‘it is in the nature of things that not many of them can be expected to have original insights’:

The outcome is hundreds upon hundreds of books which are well argued but have little or nothing to say that has not been said before. And because the quality of the argumentation is the only distinguished thing about them, and also the thing their readers as well as their writers are best at, it becomes the object of interest, and hence the criterion by which they and their authors are judged. In consequence, many professional philosophers and their students slide unthinkingly into proceeding as if philosophy is *about* arguments and they lose sight of the fact that it is really about insights. So when a philosopher comes along who really does have something new to contribute, he tends to be judged more by the quality of his arguments than by the quality of his insights – and if the former is unremarkable the latter may go unappreciated.²⁷

Waismann again cannot be bettered:

What is essential in philosophy is the breaking through to a *deeper insight* – which is something positive – not merely dissipation of fog and the exposure of spurious problems. Insight cannot be lodged in a theorem and it can therefore not be demonstrated ... It is dangerous in philosophy to hunt for premisses instead of just going over the ground, standing back and saying: look.'²⁸

Philosophical reasoning since Plato is believed to take its value from restraining the emotions so as to apprehend truth by abstract logical argument. Nietzsche thought he saw in Socrates a 'hypertrophy of the logical faculty'.²⁹ John Cottingham, himself a distinguished philosopher trained in the analytic tradition (and editor of the classic edition of Descartes's works), writes that

much Western philosophy has suffered from a ratiocentric bias – the notion that calm and detached rational analysis provides the unique key to understanding ourselves and our activities. At its worst, ratiocentrism involves a fantasy of command and control, as if by sufficiently careful use of reason we could gain an exhaustive understanding of the human condition.³⁰

The phrase ‘command and control’ suggests the coercive fantasy of rationality, that conclusions can be compelled on another, and is strikingly in keeping with the suggestion that it is the tool of the left hemisphere, whose *raison d’être* is control. However, ‘no philosophic argument ends with a QED’, wrote Waismann. ‘However forceful, it never forces. There is no bullying in philosophy, neither with the stick of logic nor with the stick of language.’³¹

Indeed, it has been argued by cognitive scientists Hugo Mercier and Dan Sperber not only that rationalising does not lead to better decisions, of which there is ample evidence, but that the capacity for reasoning arose in the first place not to help us arrive at truth: its purpose was to win arguments – whether right or wrong.³² The idea is not as novel as it seems: Burke observed that

almost the only pleasure that men have in judging [using their reason] better than others, consists in a sort of conscious pride and superiority, which arises from thinking rightly ... a pleasure which does not immediately result from the object which is under contemplation.’³³

If it is truth we are after, why do we choose the evidence that confirms our bias? Why does experiment show that providing people with reasons to change their minds often makes their position more entrenched?³⁴ Thomas Hobbes wrote in the seventeenth century that ‘arguments seldom work on men of wit and learning when they have once engaged themselves in a contrary opinion.’³⁵ Reason on its own is powerless. And, note, that is *not* simply because we are irrational (though at times we certainly may be). It is because, rather, we need to respond with the whole person, in the context of history and experience.

Argument depends on language of some kind. There is a peculiar bias towards language and naming in Western culture. East Asians solve problems significantly better when not obliged to express themselves in words, as often do Westerners, as we will see in Chapter 17; but for East Asians language scarcely appears to be involved in the process at all.³⁶ Speech is much less prized than silence in Japanese culture; silence is considered more conducive to thought. According to psychologists Timothy

Takemoto and Thomas Brinthaup, ‘Japanese culture, it would seem, is best described by the absence of words, including those to describe it’.³⁷ Visual thought is predominant among the Japanese and is preferred to verbal thought.³⁸ The Japanese language lacks a method for composing abstract nouns. *Xiǎng*, one of the basic words for ‘think’ in Chinese, is written with a glyph composed of the elements tree + eye + heart. The Chinese word that translates our word ‘concept’ means a simple symbolic impression from experience. The absence of theorising in Japanese and Chinese does not mean an absence of philosophy: philosophy is, or should be, the love of wisdom, to feel its call, not just the analysis of verbal propositions.³⁹

I believe the combination of scientism and ratiocentrism is making our vision narrower than it should be. I commented that, inside the bubble (which I would identify with the left hemisphere’s reality) we no longer see the limitations of our viewpoint – precisely because of its limitations. But nothing can prevent us from noticing that things are not working out the way we hoped. Whitehead again:

The main evidence that a methodology is worn out comes when progress within it no longer deals with main issues. There is a final epoch of endless wrangling over minor questions. Each methodology has its own life history.⁴⁰

A philosopher colleague alerted me to a good snapshot of analytic philosophy obsessively engaged in endless wrangling over minor questions.

In 1940, of all years, when Western civilisation was facing one of its most terrifying moral and existential crises, notes taken at Harvard on discussions over the year by Carnap, Tarski and Quine – respectively the leading Austrian, Polish and American analytic philosophers of their age – show that much of their discussion was devoted to working out what arithmetic *would have been* like had there been only a finite number of objects.

I am not saying that there is no place in academe for such speculation, far from it. But the complete failure by many leading analytic philosophers to engage even tangentially with the most pressing problems of a civilisation in crisis is strikingly reminiscent of fiddling while Rome burns. One might object that such was their training and expertise that we could not expect them to change. But that inescapably says something about the nature of twentieth-century analytic philosophy: its narrowness and its degree of abstraction from life. I am reminded of a remark by philosopher Jan Zwicky:

Thinking analytically is like going on a diet. Its aim is a healthy austerity of thought, a certain trimness of mind. But when it's carried too far, we're left only with a skeleton. Carried too far too often, we lose the sense that something is amiss when the patient exhibits no life. We come to take pride in our cases of polished bone.^{[41](#)}

What has happened to philosophy in our time? It has suffered the general fate of modern academic life, narrowness and sterility. Freeman Dyson puts it with customary clarity:

For most of the twenty-five centuries since written history began, philosophers were important ... They spoke not only to scholars but also to rulers. They had a deep influence in the practical worlds of politics and morality as well as in the intellectual worlds of science and scholarship ... Through all the vicissitudes of history, from classical Greece and China until the end of the nineteenth century, philosophers were giants playing a dominant role in the kingdom of the mind ... Compared with the giants of the past, [contemporary philosophers] are a sorry bunch of dwarfs ...^{[42](#)}

Philosophy has become, like science, narrowly specialised:

the debates have become so much the property of specialists who have devoted prodigious energy to devising the most intricate arguments and counter-arguments to support their views, that it is unlikely that anyone who did not have a professional or career motivation for putting in the requisite effort would willingly wade through the resulting conceptual treacle.⁴³

Once again these are the words of Cartesian scholar John Cottingham, not a man, one would have thought, to be daunted by conceptual treacle where strictly necessary. (It may not be a purely modern phenomenon though: I am reminded of the words of Friedrich Schlegel, that ‘there’s a certain sort of person for whom the exaltation of tedium is the first impulse to philosophy’.)⁴⁴ And Cottingham continues, in words that are reminiscent of the connexion between writing obscurely and getting published which we noted in the context of science (it’s ‘more difficult for reviewers to fault it’):

We learn our trade by writing doctoral dissertations, and few dissertations have been failed for being too technical or laborious, whereas a bold and transparently stated claim to which a counter-example can be found may lead to a thesis being referred back. Or again, if a journal submission manages to work through current technical debates in a manner so impressively complex that the referee cannot easily spot any flaws, it may get the benefit of the doubt. In the fierce jungle of competition, donning heavy armour against possible attack, however exhausting, sweaty, and hampering of movement, may be the safest survival strategy.⁴⁵

Great philosophers of the past, by contrast, he points out, took broad views:

If we look at Plato, or Aquinas, or Descartes, or Spinoza, or Hume, or Kant, what is striking is the *wide reach* of their thought – the extent to which it spans a great many of what we now think of as

distinct specialities or sub-specialities of philosophy. Plato, for example, has a philosophical world view which has implications for ethics and politics, for science and mathematics, for metaphysics and aesthetics; and the stamp of his philosophical vision can be clearly seen in his writings in all these areas ... In fact all the canonical figures just mentioned had a grand synoptic vision of the nature of the world, of the place of humankind within it, of the extent and limits of human knowledge, and of the best way for human beings to live.⁴⁶

In other words they addressed Plotinus's question, 'who are we?', as Schrödinger recommended that scientists should. The vision of the left hemisphere is of narrow scope; and its process of understanding is by taking ever smaller parts. But understanding always works in both directions, upwards and downwards at the same time, so that the higher levels must be presumed to illuminate the lower as much as the lower illuminate the higher.

'One can only become a philosopher, not be one', wrote Friedrich Schlegel. 'As soon as one thinks one is a philosopher, one stops becoming one.'⁴⁷ A philosopher is never in possession of the truth, but endlessly searching for it. In the middle of the twentieth century, the philosopher William Earle wrote an essay called 'Notes on the Death of Culture'.⁴⁸ In it he wrote trenchantly about the rise of what he called the Technical Philosopher, a figure who is engaged in 'professionalising' wisdom. Or rather, this new kind of philosopher steers clear of wisdom altogether, probably convinced that there isn't any. For this figure, the most shameful thing is to be thought 'edifying', followed closely by being thought 'muddleheaded':

all traditional philosophy was muddleheaded, had no idea of what it was doing, and did even that badly ... exactly what might be expected of a philosopher who intended to be edifying.

Instead this new philosopher is a philosophical worker, or 'researcher':

He would be delighted to teach his classes in a white laboratory coat ... His inquiries, investigations, and research will be embodied in a 'monograph', a short paper with the 'problem' clearly stated at the beginning, and at the end a summary of the 'results'. The monograph must also refer to the other 'literature' on the subject. The Technical Philosopher thus is short-winded; he has an instinctive distaste for the sprawling works of the nineteenth century, when philosophers sometimes sought a larger view of things.

Technical Philosophy is 'simply one sort of work for which one is paid. It should have no resonance beyond those hours'. Ideally, it takes place not in ordinary language: 'he has always had a fear of natural or ordinary language. Ordinary language is so obscure; words come dripping out of a sea of feelings and related meanings, and are logically unmanageable.' Ideally, it should be expressed in some form of artificial symbolism, 'which takes years of training to read with any ease'. The Technical Philosopher 'has always envied the mathematician, with his proofs and symbols.' By adopting such means

everything should be clear, and to some extent it is; but unfortunately the language is so impoverished that nothing of any importance can be said in it, and so artificial in form that error is perhaps more frequent in it than in our mother tongue.

And so the philosopher turns his glare on the 'muddleheaded' use of language by someone else. As Earle points out, this depends on the assumption that the language was not clear in its first usage, and must be made clear by the analysis. However, if it is not clear at first, how does the philosopher know he has 'clarified' it? And if it was already clear, why bother? As it has been pointed out, there is a problem with analysis: if the analysis can be substituted for whatever it analyses, it is tautologous; but if it cannot, it is false.⁴⁹

This assumption is combined with another 'fervent assumption',

that the philosopher himself is entitled only to analyse; that is, his work consists of tearing apart intellectually phrases others have put together. He analyses syntheses but he makes no synthesis himself ... To ask a Technical Philosopher for his vision of the world is to throw him into the worst of embarrassments. It is hopelessly to misunderstand what philosophy now is. The philosopher's answer will not try to supply that vision, or even recognise its absence; rather it will analyse the meaning of your question in order to show that it really has no meaning at all. It is left for others to supply the vision ...⁵⁰

And Earle concludes:

Now this was not always so. For the longest stretch of its history, philosophy was, embarrassing as it is to Technical Philosophy, concerned precisely with large visions and the edifying. That is, it was concerned with the human situation and what was to be done about it ... The new philosopher need know in his professional capacity *absolutely nothing* except how *words* are used ... In any event, pure knowledge has nothing to do here; it seeks absolute purity, absolute independence, and absolute irrelevance to anything anyone might conceivably be interested in. Thus has a noble discipline committed suicide.

The separation of epistemology from ethics, which arguably began with Descartes, and the prioritising of epistemology over ethics, says the philosopher David Levin, contributed to the 'acceptability of a mode of perception the character of which is grasping, possessive, and dominating. The earlier mode, more responsive, more receptive, more predisposed to be moved by ethical factors, consequently withdrew to a reduced role in our cultural life.'⁵¹ In this way the analytic frame of mind has led, as it has in science, to a fragmentation of vision, including the vision of a society. Philosophy, as Whitehead saw, is the 'very foundation of thought and of life. The sort of ideas we attend to, and the sort of ideas which we push into the negligible background, govern our hopes, our fears, our control of behaviour. As we think, we live. This is why the assemblage of philosophic

ideas is more than a specialist study. It moulds our type of civilization'.⁵² The importance of philosophy, if it is to mean anything, must lie far beyond the seminar room.

This vision – or lack of it – is what the left hemisphere's procedures lead us to. As a result, as Ernst Cassirer put it, we have amassed a huge, and ever increasing body of facts, but

unless we succeed in finding a clue of Ariadne to lead us out of this labyrinth, we can have no real insight into the general character of human culture; we shall remain lost in a mass of disconnected and disintegrated data which seem to lack all conceptual unity.⁵³

The ever-growing number of fragmented, specialist disciplines which deal with the nature of humanity, do more to obfuscate than reveal. As a result, as Scheler thought, 'one can say that in no historical era has the human being become so much of a problem to himself as in ours.'⁵⁴ An explosion of knowledge leads us only to what Bohm called 'endarkenment'.⁵⁵

Like spiritual exploration, philosophical exploration shows the fly the way out of the bottle. This is a form of enlightenment and is referred to (with deliberate paradoxical intent) as 'beginner's mind' in the Zen tradition: the freshness of insight before intellectualising dimmed it. At the end of his career, Husserl admitted that 'the first result of reflection is to bring us back into the presence of the world as we lived it before our reflection began (*Lebenswelt*)'.⁵⁶

Reality is rich and complex, and I have suggested that part of it is always hidden from us. This is not just my take: it was, in different ways what Bacon meant when he said that 'the subtlety of Nature is greater many times over than the subtlety of the senses and understanding', what Heraclitus meant by saying that 'Nature loves to hide', what Einstein meant by 'Nature hides her secrets', and what Heidegger meant by 'the clearing in which Being stands is itself at the same time concealment'.⁵⁷ To quote Cottingham again:

the way each of us makes sense of who we are and our relation to the world is a fearsomely complex process of which our

intellectualising is only the thinnest of surfaces. At the very least this suggests the need for a certain humility about the philosophical project of ‘making sense of ourselves and our activities’. We need to recognise the limitations of intellectual analysis, and the way in which insight is achieved not just by the controlling intellect, fussily classifying and cataloguing the pieces of the jigsaw, but by a process of *attunement*, whereby we allow different levels of understanding and awareness to coalesce, until a picture of the whole begins to emerge.⁵⁸

Analysis makes explicit what we are aware of in the first instance through intuition. At its best, it achieves a ‘fit’, whereby our intuitions get to be nudged and in turn our reason allows itself to be modified, somewhat like the process of attunement envisaged by Cottingham. Ultimately the result is that we trade off some of our intuitions against others.

An admirable process leading to an admirable achievement – but it carries risks. In making things explicit, one enters a labyrinth of ever-receding definitions, each one supposedly to be refined at the next turn in the labyrinth, a process which in reality is never to be completed. Consciousness, for example, let us say with Descartes, is a ‘thinking thing’, *res cogitans*. Well, I’m glad we got that clear. But what is thinking? And what is a thing? Unless the answers already include the possibility of human consciousness as we understand it, they fail. To understand these elements, ‘thinking’ and ‘thing’, they need once more to ascend, as well as to descend, the ladder of explanation. Something at a lower level of analysis does not account for, but merely re-describes, the phenomenon in which we are interested, often less helpfully. We understand human meaning by seeing what it constitutes, not just that of which it is constituted.

And this is not so much because humans are different from inanimate systems – indeed they are, but that is not the key point at issue. It is that the scientific process of breaking things down *never* offered an understanding of what something actually *is*, even if inanimate. It was only an understanding of its mechanism, and a partial one at that – a very different matter. Defining, and ever refining the definition, will never answer human questions. It is not uncommon, writes Cottingham,

for a philosopher to say he has produced a ‘theory’ of pleasure, or a ‘theory’ of action, when all that is being offered is an extended definitional and conceptual discussion. It is very easy to be caught up in the intricacies of analysis, and to mistake the introduction of more and more technical terms for a substantive explanatory advance ... What is needed is not philosophical analysis but philosophical *synthesis* – not chopping things into parts, but linking them together.⁵⁹

In most areas of philosophy we need both: but analysis must be in the service of synthesis, the left hemisphere in service of the right. On this topic, there is a subtle observation by the astrophysicist and mathematician Sir Arthur Eddington. If we do not analyse at all, we do not separate distinctly enough. But if we carry analysis too far, ‘the parts become so simple that they are indistinguishable, their indistinguishability confuses them in our observational knowledge and, in a sense, undoes the separation which the analysis has effected.’⁶⁰ To take a practical and familiar example: analysing a piece of music into phrases may give information; persisting in analysis eventually yields but single notes, that individually have no meaning and therefore yield no information whatsoever. The structure of matter illustrates the same problem: there are only a small number of elementary particles (we are told), and analysis yields progressively less information as they are approached. In other words, at an intermediate level we can usefully distinguish one material aggregation from another; at a deeper level of analysis we are left with a bunch of quantum phenomena. The uniqueness of what we had seen was in the *Gestalt* which we have just destroyed. We need to know about parts only because it can help us see how the parts *relate*. Take away the relations and we are left with nothing. Similarly, the point of a narrow and detailed specialisation is to provide knowledge that can be re-integrated into an understanding of the whole. On its own it is virtually useless.

Employing analysis, which works from the outside of its object, without listening to intuition, which inhabits the matter at hand from the inside, is like looking for the power of a poem in the translation, where it cannot be found, and then when one cannot find it, denying it was there in the original.

Even if viewed merely as an agent of consensus, unbalanced rationality does not compare favourably with a less purely rationalistic, more spiritually aware exploration of the world. Compare the great traditions of the East, in which reasoning has not been the single privileged path to truth, and where there is yet remarkable consensus over space and time, with Western cultures in which it has, and where there isn't.

EXPLICIT AND IMPLICIT REASON

There are, then, two widely held and equally mistaken beliefs about reason. On the one hand, it is believed by many that, if properly followed, reason should compel all rational people to the same conclusions, and that these conclusions have ‘objective’ truth – the fallacy of ratiocentrism (a cousin to scientism). This was given concrete expression by Leibniz, in his projected ‘calculus ratiocinator’, a computer that would transform – indeed extinguish – philosophical discourse. ‘When differences arise’, he wrote,

there will be no more disputation between two philosophers than between two accountants. For it will be enough for them to take up their pens and sit down at the abacus, and say to one another (calling in a friend if they want): let’s calculate.⁶¹

On the other hand, it is believed by some that, because this very point of view is so blatantly absurd, reason is somehow discredited, and we can act as though we owed nothing to it – the reciprocal fallacy, that of postmodernism.

But it is only the extreme claims made for rationality that are discredited. There is no way we can have discourse without some reliance on rationality, never mind without reason, which is the basis of a shared culture and a civilisation. One could claim that only poetry or the paradoxical pronouncements of mystics attain what can be called truth, but that too is unbalanced: it would clearly be a very brave – many would say, foolish – person who claimed that rational discourse led us nowhere; although it would also be foolish to deny that such discourse needs to know its own limitations, and that poetry, metaphor, myth, narrative and paradox play an important role in taking us beyond its limits. I hear as often the words of Pascal the mathematician: ‘It is equally excessive to shut reason out and to let nothing else in’.⁶²

In trying to come to a better understanding of the proper use of reason, it may help to distinguish what one might call ‘explicit reason’ from ‘implicit reason’. I have emphasised that the left hemisphere seems able to deal only with what is relatively explicit, and that it is the right hemisphere

that enables us to understand implicit meaning of all kinds; but I may seem to have been making a point that is more pertinent to the arts than to science or philosophy. All the same, as I have pointed out, the paths used by scientists, mathematicians and philosophers to reach conclusions are often implicit, and are only subsequently and incidentally coupled to an explicit justification. And I suggest that explicit reasoning brings with it hazards. As Heraclitus noted, ‘an unapparent harmony is more powerful than an apparent one’.⁶³

Surely it is always right that nothing should be taken for granted? Not always so. Some things can only be experienced or understood when they are not put to analysis. This is not because analysis defeats them, but because they defeat analysis. The effect of the direct glare is to banish the penumbra of myriad delicate threads that make it what it is and connect whatever it is to what nourishes it and gives it life, like the roots of a plant or the vessels that feed the heart and which it feeds. Snatch the plant from the soil, snatch the heart from the body, and they not only die, but they can no longer be understood for what they are. The effect is to substitute something that can be analysed for something that cannot: to change the nature of what is examined.

One of the best explorations of the distinction between explicit and implicit reason was made by John Henry Newman. In a sermon delivered at Oxford University on the 29 June 1840, he offers a number of insights; in particular that implicit reason – which is a living, embodied human skill – encompasses many elements, unlike explicit reason, which is a useful, but single mechanical procedure. He describes the mind in action, as it ‘ranges to and fro, and spreads out, and advances forward’,

not unlike a clamberer on a steep cliff, who, by quick eye, prompt hand, and firm foot, ascends how he knows not himself; by personal endowments and by practice, rather than by rule, leaving no track behind him, and unable to teach another.⁶⁴

And he makes a similar point about how we become convinced of the rightness of a position:

conviction for the most part follows, not upon any one great and decisive proof or token of the point in debate, but upon a number of very minute circumstances together, which the mind is quite unable to count up and methodize in an argumentative form ...⁶⁵

He also makes a point that should be familiar in relation to the hemispheres. Reasoning is not the same as the retrospective account we give of it – an analysis which may leave important elements out:

Here, then, are two processes, distinct from each other, – the original process of reasoning, and next, the process of investigating our reasonings ... In other words, all men have a reason, but not all men can give a reason ... The exercise of analysis is not necessary to the integrity of the process analysed. The process of reasoning is complete in itself and independent. The analysis is but an account of it; it does not make the conclusion correct; it does not make the inference rational. It does not cause a given individual to reason better.⁶⁶

The right hemisphere is more involved with the living process as it happens, the left with the post-mortem dissection that occurs *once it has stopped*. The representation of reason given by retrospective analysis is bound to be only a partial account of the true reasoning process, and Newman compares the relationship to that between a portrait and the living individual it portrays:

How minute is the defect in imitation which hinders the likeness of a portrait from being successful! How easy is it to recognize who is intended by it, without allowing that really he is represented! Is it not hopeless, then, to expect that the most diligent and anxious investigation can end in more than in giving some very rude description of the living mind, and its feelings, thoughts, and reasonings ... frequently we do not recognize our sensations and ideas, when put into words ever so carefully. The representation seems out of shape and strange, and startles us, even though we know not how to find fault with it.⁶⁷

The reasons we formally adduce in moral inquiries, 'are rather specimens and symbols of the real grounds, than those grounds themselves ... hints towards, and samples of, the true reasoning';⁶⁸ and too great a focus on analysing the process of reason, Newman points out, has some unhelpful side-effects of which we are not always sufficiently aware, particularly in the area of morality and religion. This is because of

its weakening the springs of action by inquiring into them; its stimulating to controversy and strife; its substituting, in matters of duty, positive rules which need explanation for an instinctive feeling which commands the mind; its leading the mind to mistake system for truth, and to suppose that an hypothesis is real because it is consistent ... ⁶⁹

However, all such objections, he wisely concludes, important though they are, should lead us not to distrust, and certainly not to abandon, explicit rational processes, merely to use them with appropriate caution. It is hard to find such a balanced account of reason in the debates of today.

The lack of a rational understanding of the limits to reason may prove fatal. The coherence of a civilisation depends on accepting the reality and value of principles which we do not, and perhaps never can, fully understand. In all societies hitherto this has been achieved by the influence of knowledge embodied in traditions, sometimes religious, that asked for acceptance by an appeal to imagination, not to reason alone. 'The most dangerous stage in the growth of civilization', wrote Friedrich Hayek,

may well be that in which man has come to regard all these beliefs as superstitions and refuses to accept or to submit to anything which he does not rationally understand. The rationalist whose reason is not sufficient to teach him those limitations of the powers of conscious reason, and who despises all the institutions and customs which have not been consciously designed, would thus become the destroyer of the civilization built upon them. This may well prove a hurdle which man will repeatedly reach, only to be thrown back into barbarism ... ⁷⁰

Reason does in fact demonstrate its own limits, its incompleteness. However, this is so much a trade secret that the answer to Stanley Fish's question, 'Does reason know what it is missing?' is: 'very rarely, it would seem'. As he puts it,

What secular reason is missing is self-awareness. It is 'unenlightened about itself' in the sense that it has within itself no mechanism for questioning the products and conclusions of its formal, procedural entailments and experiments.⁷¹

But there exist minds that are 'enlightened' in this respect. Pascal, one of the greatest philosopher-mathematicians that ever lived, nonetheless said that 'the ultimate achievement of reason is to recognize that there is an infinity of things which surpass it. It is indeed feeble if it can't get as far as understanding that.'⁷² Kant demonstrated the limitations of reason in what are called his four 'antinomies' (or paradoxes): in each case reasoning about a fundamental aspect of reality leads equally, he claimed, to a conclusion *and* to its opposite. In the last century Kurt Gödel demonstrated definitively that every formal system is incomplete, in that each leads to conclusions that can be shown to be theorems of the system, but cannot be proven within the system. Mathematician and philosopher Greg Chaitin claims that 'an infinite number of true mathematical theorems exist that cannot be proved from any finite system of axioms'.⁷³ It is not rational to assume, without evidence, that rationality can disclose everything about the world, just because it can lead us to the disclosure of many important elements.

Equally, just because rationality can't solve many problems is not a reason to give up on it. In 1936 Alan Turing addressed the so-called 'halting problem' – whether, from the description of any computer program and an input, it is possible to determine if it will eventually come to a conclusion, or simply run for ever – by showing that a general algorithm for solving all halting problems does not exist. Of this, Chaitin writes:

No algorithm, no mathematical theory, can ever tell us which programs will halt and which will not ... This conclusion does not mean that proofs are no good, and I am certainly not against reason.

Just because some things are irreducible does not mean we should give up using reasoning.

However, of mathematics after Gödel, he concedes:

It turns out that an *infinite number* of mathematical facts are irreducible, which means no theory explains why they are true. These facts are not just computationally irreducible, they are logically irreducible. The only way to ‘prove’ such facts is to assume them directly as new axioms without using reasoning at all ... Given any finite set of axioms, we have an infinite number of truths that are unprovable in that system.

‘Irreducible principles – axioms – have always been a part of mathematics’, he continues. It’s just that there are ‘a lot more of them out there than people suspected’.⁷⁴

Of course one does not need to rely on abstruse mathematics to see the limitations of reason. Anyone who understands poetry, drama, ritual, narrative, music, painting, architecture, or the sheer beauty and majesty of the natural world – or for that matter has ever fallen in love – can see that ultimate meaning will *always* lie beyond what reason can conceive or everyday language express.

How do we best employ reason, then, in the search for truth? To insist on reason alone is deeply irrational, not to say the sign of a mental illness, and I have touched on some of the many reasons above. ‘There is nothing so conformable to reason’, wrote Pascal, speaking of the moment at which reason appreciates its own limitations, ‘as this disavowal of reason’.⁷⁵ But to abandon reason altogether is also deeply irrational. ‘Reason seems able to overthrow the deification of everything but itself,’ writes Stanley Cavell. And yet

to imagine that what is therefore required of us is a new rage of irrationality would be about as intelligent as to imagine that because heaven rejects the prideful man what it craves is a monkey. For the point of forgoing knowledge is, of course, to know.⁷⁶

So we must use our discernment as to how much, of what sort, in what way, and to what purpose. 'Where's the certainty in that?' you may say. 'Isn't it a matter of discernment which judgments we prefer?' I can only say that if you are still hoping for something certain and above human judgment, please don't let me disturb your sleep.

REASON'S PROGENY

Improvement makes strait roads; but the crooked roads without Improvement are roads of Genius.

—*William Blake*¹

Ambiguity is of the essence of human existence, and everything we live or think has always several meanings.

—*Maurice Merleau-Ponty*²

AT THE BEGINNING OF THE PREVIOUS CHAPTER I GAVE TWO CONTRADICTORY definitions of reason, one very much the product of the left hemisphere's take on the world; the other, of the right's. I argued that we need both; that the right hemisphere's broader view of the world can accommodate both but that the left hemisphere is prone to regard its version of reason, rationality, as sufficient and, as a result, produces a narrow, ratiocentric account of the world that is deeply misleading. In this chapter I want to look in more detail at reason's progeny: the pairs of twins reason begets to help us approach truth. Again, one of each pair of twins claims paternity by the left hemisphere; the other, by the right. And once again we shall be led astray if we attend only to the dominant left twin rather than see that truth is more fully apprehended if both are enlisted, but with the left twin ultimately in the service of the right.

ABSTRACTION VS EMBODIMENT

‘The history of computers is often told as a history of objects’, writes Chris Dixon. ‘In fact, it is better understood as a history of ideas, mainly ideas that emerged from mathematical logic, an obscure and cult-like discipline that first developed in the nineteenth century.’³ Earlier I made the analogy between the capabilities of apparently intelligent logic and those of the apparently unintelligent computer. If you think that is far-fetched, recall that one of the landmarks of philosophy in the last hundred-odd years was Frege’s development of his *Begriffsschrift* (or ‘concept notation’), a formal language of meaningless symbols manipulated by precise rules, exactly as a computer operates. For the first time in philosophy, truth is specified by content-free, manipulable structures *separately* from any meaning-giving context, in a fascinating rupture of the link that, in the real world, indissolubly binds form and meaning.

Music is as near an example of pure form as one might find: it does not refer outside itself. And yet its meaning is profound. Meaning arises richly and inevitably out of any *embodied* form: but it must be embodied. Only in algebra, which is disembodied, can form and meaning be separated. Frege’s ‘concept notation’ is a kind of algebra which respects logical structures, but is indifferent to meaning. This, then, is the ultimate triumph of decontextualisation and abstraction.⁴

However, that is what one might have thought of as the downside of a machine – not the upside of a person. According to two distinguished computer scientists who won the Turing Award for services to artificial intelligence, the computer necessitated a form of logic ‘purged’ of meaning – developed by the work of Frege, Whitehead and Russell –

often referred to as the ‘symbol game’ ... played with meaningless tokens according to certain purely syntactic rules. All meaning had been purged ... Thus progress [in AI] was first made by walking away from all that seemed relevant to meaning and human symbols.⁵

The left hemisphere tends to abstraction in a number of ways. One is its dependency on linguistic thought. 'As soon as I have expressed something in a word', wrote Erich Fromm,

an alienation takes place, and the full experience has already been substituted for by the word. The full experience actually exists only up to the moment when it is expressed in language. This general process of cerebration is more widespread and intense in modern culture than it probably was at any time before in history ... words more and more take the place of experience. Yet the person concerned is unaware of this. He thinks he sees something; he thinks he feels something; yet there is no experience except memory and thought. When he thinks *he* grasps reality it is only his brain-self that grasps it, while he, the whole man, his eyes, his hands, his heart, his belly, grasp nothing – in fact, *he* is not participating in the experience which he believes is *his*.⁶

The 'brain-self' versus the 'whole man' – for which one can read the left hemisphere vs the right.

As we have seen, the left hemisphere has a greater affinity for categorisation and the general than for the unique and individual, and it deals with what has been relatively disembodied and removed from context. Once again, it is clear that all these preferences involve distancing from nature and the experienced world, in which everything is unique and individual, and dwells in embodied form within a context. In this very fact, the right hemisphere is more veridical, since real and existing things are never equal. To quote Nietzsche:

Every word instantly becomes a concept precisely insofar as it is not supposed to serve as a reminder of the unique and entirely individual original experience to which it owes its origin; but rather, a word becomes a concept insofar as it simultaneously has to fit countless more or less similar cases – which means, purely and simply, cases which are never equal and thus altogether unequal. Every concept arises from the equation of unequal things. Just as it is certain that one leaf is never totally the same as another, so it is

certain that the concept “leaf” is formed by arbitrarily discarding these individual differences and by forgetting the distinguishing aspects.⁷

This doesn’t mean there is something intrinsically *wrong* with the left hemisphere’s thought processes – unless they get mistaken for reality. A map may be very helpful in orientating you in the world, and helps you to understand aspects of it better; it can help you see further, but only when what it tells you has been returned to the world in front of your eyes. If you start to believe the map is the world, you are lost.

A map gives one power to manipulate, to understand the *form*, while at the same time, and not coincidentally, distancing one from the substantial world which gives it content. General terms, according to Charles Fried,

are attempts to sweep a large set of particulars under a single conceptual rug; but it is an attempt doomed to failure. General terms have no objective correlates; they are merely compendia of particulars collected together for our convenience in terms of similarities we note for our purposes. To say that general terms have no objective reality is to say *first* that general terms do not of themselves identify the particulars subsumed under them, and *second* that therefore the process of subsumption is a value-laden process, one which refers to human goals and purposes.⁸

Conceptualising anything is a way of asking ‘what it can do for us’, says Bergson.⁹ One of the drives behind cartography was the subduing of subject peoples, or at least the acquisition of their potential mineral or material wealth. Britain’s Ordnance Survey, one of the world’s largest purveyors of detailed maps, takes its name from its original military purpose, the mapping of Scotland in the aftermath of the Jacobite rebellion of 1745, in order to make sure that any future rebellion could be more easily quelled.

In *The Scientific Outlook*, Bertrand Russell wrote:

Scientific thought [by which he meant not imaginative scientific work, but rational, linear thinking] is ... essentially power-thought –

the sort of thought, that is to say, whose purpose, conscious or unconscious, is to give power to its possessor. Now power is a causal concept, and *to obtain power over any given material one need only understand the causal laws* to which it is subject. This is an essentially abstract matter, and the more irrelevant details we can omit from our purview, the more powerful our thoughts will become.¹⁰

He then goes on to point out that the farmer who tills the field and grows the corn makes less money from his produce than the railway companies that transport it, from whom it is more remote and for whom it is relatively abstract; and that the dealer on the stock exchange, for whom it is entirely abstract, and who is as remote as one can get from it, stands to make much more than either of them. Thereby he correctly exposes one of the most unattractive aspects of capitalism; it remains, however, a curious way to recommend a style of thought.

This was a matter that particularly concerned William James. '*The intellectual life of man*', he wrote '*consists almost wholly in his substituting a conceptual order for the perceptual order in which his experience originally comes.*'¹¹ In similar vein, Kierkegaard had commented drily:

What the philosophers say about reality is often as disappointing as a sign you see in a shop window: Pressing Done Here. If you brought your clothes to be pressed, you would be fooled; for the sign is only for sale.¹²

James's philosophy could be seen as one lifelong battle on behalf of experience against the fallacies of abstraction and representation: not offering the sign for sale, but actually doing the pressing. Where Plato had elevated ideas, which he supposed to be real and eternal, and disparaged the world of experience, which he claimed to be a poor copy of perfect ideas, James aimed to redress the balance. Naturally, like all philosophers, he works a lot at the abstract level – how could he not? But it is always in the service of a fuller understanding of the phenomenal world, not, as so often happens, a *substitution for it*. He is not (nor am I) against conceptualisation. Concepts, he writes,

are precious in themselves ... apart from their original use, and confer new dignity upon our life ...so long as their original function does not get swallowed up in the admiration and lost. That function is of course to enlarge mentally our momentary experiences by *adding* to them the consequences conceived; but unfortunately, that function is not only too often forgotten by philosophers in their reasonings, but is often converted into its exact opposite, and made a means of diminishing the original experience by *denying* (implicitly or explicitly) all its features save the one specially abstracted to conceive it by.¹³

The abstractions that we create through language seem to be real and are taken by the unwary for things. Although, general, single in nature and withdrawn from the experiential world, they are always derived from particular, instantiated, complexes, not vice versa. The abstracting tendency does, as James is very ready to admit, have its uses in many cases and places; but it can be remarkably inefficient as a way of approaching or dealing with experience, and it certainly needs to be kept in check.¹⁴ For as Heisenberg warned: 'The concepts initially formed by abstraction from particular situations or experiential complexes acquire a life of their own'.¹⁵ Which of us could deny this in the world of today? 'It is not always remarked', wrote the philosopher Max Müller,

that we men have almost entirely left the sphere of purely intuitional knowledge, and that the world in which we live and move and have our being is a world of concepts; a world which we have created ourselves, and which, without us, without the spectators in the theatre, would vanish into nothing.¹⁶

Long before this, Berkeley had criticised the 'false principles ... amongst all which there is none, methinks, hath a more wide influence over the thoughts of speculative men, than this of *abstract general ideas* ...'¹⁷ Hume called this insight of Berkeley's 'one of the greatest and most valuable discoveries that has been made of late years in the republic of letters.'¹⁸ There is a clear connexion between the will to power of the left

hemisphere, and a tendency to try to make reality conform to our theory; wisdom lies in conforming one's theory as far as possible to experience.

Pronouncements emanating from management culture are the worst. The bureaucratic mind prefers nouns to verbs, abstract nouns to concrete nouns, and, in verbs, the passive to the active voice. 'Seat-belts must be worn', just as 'the beaker was placed ...' To some extent each of these preferences is aligned with the proclivities of the left hemisphere. While much of language is of course processed in the left hemisphere, there is a tendency for concrete nouns to be processed more bilaterally than abstract ones, which are predominantly (though not exclusively) processed in the left.¹⁹ Left temporal brain-damaged patients perform significantly better with concrete than abstract words, for which the left superior and middle temporal gyri and insula appear to be crucial.²⁰ And disrupting the left temporal lobe using TMS causes impairment in processing words with abstract referents, while disrupting the equivalent right temporal area interferes with processing words with concrete referents.²¹ Equally, passive constructions in languages as syntactically divergent as English and Japanese cause additional recruitment of left hemisphere regions, particularly the left inferior frontal gyrus and posterior perisylvian regions.²² Only one study found that the right inferior frontal gyrus was also involved, which the report's authors attributed to the need for 'effortful syntactical reanalysis':²³ the right hemisphere is recruited in direct proportion to the difficulty of meaning construal.²⁴

Whitehead emphasised that there was 'a right adjustment' to be observed – a proper measure and manner – in the deployment of abstraction. And he made the wise observation that abstraction, like everything else, can be valuable *up to a point*, but that too much emphasis on it starts to be more of a handicap than an asset:

the higher animals are distinguished from mere life, by their abstractions, and by their use of them. Mankind is distinguished from animal life by its emphasis on abstractions. The degeneracy of mankind is distinguished from its uprise by the dominance of chill abstractions, divorced from aesthetic content.²⁵

The word 'aesthetic' here is used in its strict sense, referring to sense perception and feeling, not just to an appreciation of beauty – though he was very far from denying the value of beauty. Whitehead, like Schelling, believed – as do I – that reality is neither undiscoverable, nor discoverable by the intellect alone, but by the whole embodied being, senses, feeling, intellect and imagination.

'The first thing the intellect does with an object', writes James – and for 'intellect' we may substitute here 'left hemisphere' – 'is to class it along with something else.' It is Procrustean: it simply chops off all that makes one individual different from another. It was this that Nietzsche meant by his saying that 'every concept arises from the equation of [what are in reality] unequal things'. ²⁶ And James continues:

But any object that is infinitely important to us and awakens our devotion feels to us also as if it must be *sui generis* and unique. Probably a crab would be filled with a sense of personal outrage if it could hear us class it without ado or apology as a crustacean, and thus dispose of it. 'I am no such thing', it would say; 'I am MYSELF, MYSELF alone'. The next thing the intellect does is to lay bare the causes in which the thing originates. Spinoza says: 'I will analyse the actions and appetites of men as if it were a question of lines, of planes, and of solids.'²⁷

One of James's greatest contributions to philosophy was to see this as one of the principal causes of derailment in our thinking. He called it 'vicious abstractionism'. What he meant by this was that we replace, without even being aware of it, something concrete and particular with something abstract and general, on the basis that it has a feature that entitles it to belong in a certain category. At that point, instead of the process of categorisation *adding* to the 'originally rich phenomenon', by associating it with other ideas, it *strips* what it has categorised:

Abstraction, functioning in this way, becomes a means of arrest far more than a means of advance in thought. It mutilates things; it creates difficulties and finds impossibilities; and more than half the trouble that metaphysicians and logicians give themselves over the

paradoxes and dialectic puzzles of the universe may, I am convinced, be traced to this relatively simple source. *The viciously privative employment of abstract characters and class names* is, I am persuaded, one of the great original sins of the rationalistic mind.²⁸

James was, of course, not alone in seeing this. His philosophical colleague Dewey thought that neglect of context was ‘the greatest single disaster which philosophic thinking can incur’.²⁹ He was surely right. To quote Aristotle, ‘law is universal but about some things it is not possible to make a universal statement which shall be correct’.³⁰ The more philosophy abstracts and generalises, the more it distances itself from a world in which all that is is unique. All our perceptions and thoughts are parts of a living, embodied organism, uniquely embedded in a place and a moment in time. In an arresting phrase, Bergson points out that ‘our concepts have been formed on the model of solids’.³¹ Given that concepts are inevitably immaterial, this may seem paradoxical. What he means is that when concepts stand in for whatever it is that exists in the world of experience, and therefore within time, they immobilise and sunder the natural flow of the entity in question: they *freeze*, so to speak, elements that are in their very essence *dynamic*, and they separate into parts the essentially inseparable. Conceptualisation is a form of congelation, freezing in time.

It may be fairly argued that it is hard to do philosophy in any other way (though both the so-called ‘Pragmatists’ and the ‘phenomenologists’ made significant attempts), but in that case we should be appropriately modest about what philosophy can achieve. ‘All philosophers suffer from the same defect’, wrote Nietzsche,

in that they start with present-day man and think that they can arrive at their goal by analysing him. Instinctively they let ‘man’ hover before them as an *æterna veritas* [timeless truth], something unchanging in all turmoil, a secure measure of things ... A lack of historical sense is the congenital defect of all philosophers ... but everything has evolved; there are no *eternal facts*, nor are there any absolute truths. Thus *historical philosophising* is necessary henceforth, and the virtue of modesty as well.³²

As usual with Nietzsche, this is an extreme statement of a much-needed contrarian point of view. While, as I am arguing, there are indeed no ‘eternal facts’ or ‘absolute truths’, there are certainly enduring realities, ones that are recurrent, too, in many different cultures, and ones on which we may yet hope to agree if we are reasonable people. ‘There is no merit’, wrote the philosopher and social anthropologist Ernest Gellner,

in the contemporary exaggeration of the valid point that experience is never pure; indeed it is not, but there are very marked and narrow limits to the extent to which it can be corrupted, and hence the reverence for experience makes an enormous and salutary difference. ³³

One ground for believing that we might agree in our experience is the fact that we share our embodied nature – which even analytic minds, however much they may dream of being brains in vats, cannot escape. As Lakoff & Johnson make clear, metaphor is not an embellishment of thought, but its very ground.³⁴ The form (metaphor) is not *added* to the thought, but is itself the stuff of thought, and takes us back to bodily experience; which is probably yet another reason why the right hemisphere is better at appreciating metaphor than the left. It understands that language is embodied.

And literally so. Language as a whole evolved out of the motion (and emotion) of the body, as I argued in *The Master and his Emissary*. Reason, too, as Lakoff and Johnson point out, originates in the body:

Reason is evolutionary, in that abstract reason builds on and makes use of forms of perceptual and motor inference present in ‘lower’ animals ... Reason is thus not an essence that separates us from other animals; rather, it places us on a continuum with them ... Reason is not completely conscious, but mostly unconscious. Reason is not purely literal, but largely metaphorical and imaginative. Reason is not dispassionate, but emotionally engaged ... Since reason is shaped by the body, it is not radically free, because the possible human conceptual systems and the possible forms of reason are limited. In addition, once we have learned a

conceptual system, it is neurally instantiated in our brains and we are not free to think just anything.³⁵

Here the word reason is being used in its broad sense; rationality, in the narrow sense, then arises out of reason, dangerously aspiring to leave its embodied nature behind.

Abstraction simplifies. For years, at least until behavioural economics came on the scene, classical economists simply assumed that we, the actors in the economy, all behaved ‘rationally’, by which they meant according to their own abstract theory. That’s to say we ‘rationally’ and single-mindedly pursue ‘utility maximisation’ (getting the most we can for ourselves) to the exclusion of any other consideration. In a more recent twist on the idea (rational expectations theory), they even assume that our beliefs about what will happen in the future are themselves determined by our ‘rational’ adherence to what their theory says will happen. It’s as if we are robots programmed to behave according to their theories. We have all seen where such theories got us. The point is that we are vastly more complex than any machine – or the mechanical model that can be erected in our place. We do not perform as the model of *homo economicus* says we should in maximising our benefit; and at least one reason is that there is more to life than maximising our benefit. We often willingly and knowingly prefer other ends, such as being kind, charitable, or creative – or having children. You can, of course, ‘factor’ these in, as rational choices that make us happy, but as you do so the definition of the word ‘rational’ slips out of control and becomes complex beyond calculation. Consider: adversity is also a part of fulfilment. Serendipity, including serendipitous mistakes, leads us where no-one foresaw. Turns of events can’t be predicted, and neither can the responses of others. Our objectives change, and are, in any case, ambiguous. Nor is there anything irrational in having incompatible desires.

Note the assumption that the failing is in humanity if we don’t fit the model, not that there is a failing in the model if it doesn’t fit humanity: the map is, it would seem, more real than the terrain.

All abstractions are only our own simplifications of something that came to us originally in the flesh and blood as perceiving, sensate, intuiting beings, enmeshed in an unfathomable network of human society and its history. ‘Abstraction’, according to John Kay, ‘is the process of turning complex problems we cannot completely describe into simpler ones that we

think we can solve. But gauging which simplification is appropriate requires judgment and experience. Our simplifications are idiosyncratic and subjective.’³⁶ And in testing certain features of human decision-making, the circumstances have to be altered and simplified to yield artificially clear objectives, divorced from any context. In doing so the model-makers ‘are substituting a problem their methods can solve for the problem we actually face’.³⁷

Rationalistic deductions apply only within the bounds of an abstract model, not in real-world situations, and thus need to be balanced by an intuitive grasp of the whole. ‘The belief that models are not just useful tools but are capable of yielding comprehensive and universal descriptions of the world blinded proponents to realities that had been staring them in the face’, wrote Kay of leading Western economists prior to the crash of 2008:

That blindness made a big contribution to our present crisis, and conditions our confused responses to it. Economists – in government agencies as well as universities – were obsessively playing *Grand Theft Auto* while the world around them was falling apart.’³⁸

Cognition arises out of emotion, not the other way round. Abstraction literally means something that has been ‘dragged away’ from the context in which it lies, as if one were able to pull the bones out of a body. And abstraction is fine – for an intermediate process. But, to be of any use, what is abstracted must live once more: it has to be returned, as if the sinews, flesh and blood were given back to the bones. As William James says:

whatever elements an act of cognition may imply besides, it at least implies the existence of a *feeling* ... Beautiful is the flight of conceptual reason through the upper air of truth. No wonder philosophers are dazzled by it still, and no wonder they look with some disdain at the low earth of feeling from which the goddess launched herself aloft. But woe to her if she return not home to its acquaintance ... every crazy wind will take her, and like a fire-balloon at night, she will go out among the stars. ³⁹

Let me take an example. In 1984, the moral philosopher Derek Parfit set out his so-called Repugnant Conclusion. He formulated it thus:

For any possible population of at least ten billion people, all with a very high quality of life, there must be some much larger imaginable population whose existence, if other things are equal, would be better even though its members have lives that are barely worth living.⁴⁰

(By ‘better’, Parfit means that the ‘total amount of happiness’ would be more.) According to the Stanford *Encyclopedia of Philosophy*, ‘as the name indicates, Parfit finds the Repugnant Conclusion unacceptable and many philosophers agree. However, it has been surprisingly difficult to find a theory that avoids the Repugnant Conclusion without implying other equally counterintuitive conclusions.’ If that is true, it suggests to me that this could well be a case where the conclusion sits in judgment on the methods used to reach it, not the methods on the conclusion. If your line of thinking leads to a conclusion that flies in the face of any kind of wisdom, it is surely worth considering that there is a flaw in the thinking.

My thoughts about this are those of an outsider, therefore inevitably naïve. However, I’d like to think that practitioners in any field might be tolerant enough to welcome an occasional view from outside. I don’t pretend, here or elsewhere, to have ‘answers’ to philosophical riddles. I can only offer a perspective, one which might provide a new way of looking at them, rooted in knowledge of the brain. And here, as often in modern academic philosophical debate, it seems to me that hemisphere balance has been lost somewhere along the line.

In the first place, there is no sacrifice of happiness involved for somebody who doesn’t exist and never will do, and therefore no need to ‘remedy’ this by bringing ‘them’ into being. Happiness is an *experience*, one that can only exist for an actual human being, and, for the non-existent human being, happiness cannot arise. The potential for ‘that person’ to have existed (or not) only means something once that person actually exists (that is, once I exist there is a meaning to the thought that I might never have existed, but until then not). ‘That person’, that ‘I’, has no referent and is unknowable, because he or she is not sitting *in potentia* in an ideal space somewhere until summoned up into daylight by the forces of life, but would

be a genuinely new, in important senses unforeseeable, entity that it makes sense to talk about only once existent.

And, by the way, such is the freshness of creation, we also can't know in advance what sort of quality of life this person might have: given the very same circumstances he or she might be content or miserable, a matter of personal disposition. Happiness is not as dependent on circumstance as utilitarian and consequentialist philosophy tends to assume. We are not the interchangeable counters of this calculus: we are not only born different, but then go on to forge, to an extent, the different persons that we become.

In the second place, you can't sum 'happineses' in order to see how much 'Happiness' with a capital H there is in the world. Happiness is not some thing you can have: brief acquaintance with life as it is lived outside the seminar room would suggest that this 'thing' doesn't exist. (It's that trick the Greeks played on us, again, by inventing abstract nouns.) Being happy is rather something you must enter into. All that exists is the mode of being of those who exist, and for them happiness is more of an adverb than a noun. There is only the quality of happiness in the way a unique individual has a life. There isn't a tank of Happiness where the ballcock rises as more and more people feed their pipes into it. And if you really can't get by without summing something, then the sum of billions upon billions ('some much larger imaginable population') of people's wretchednesses ('lives that are barely worth living') is not something that any sane person could possibly think desirable.

These thoughts work for me – which is possibly all one can hope for – no doubt not for Kant's *Denker von Gewerbe*.⁴¹ It seems to me, in sum, that it is not so much the conclusion that is 'repugnant', but the mental processes that lead to it.

Serious moral thought can never be about the right calculus – how much one should give, or how many people one should save – but about a whole change of relationship to the world. A rationally achieved 'equilibrium' position in one's relationship to the world is a bureaucratic notion, that could be enforced by an administration, without necessarily having any intention, or power, to engage the moral sense at all. Cottingham again:

Abstract, decontextualised, psychologically jejune, detached from the drama of the human journey (the journey from complacency, through suffering, toward moral and psychological growth), the

‘equilibrium’ it promises seems all too abstract and intellectualised a notion to provide a proper way of addressing the deep ethical challenges of the human condition.⁴²

His assessment is in line with that of Dewey:

Thinking takes place in a scale of degrees of distance from the urgencies of an immediate situation in which something has to be done. The greater the degree of remoteness, the greater the danger that a temporary and legitimate failure of express reference to context will be converted into a virtual denial of its place and import. Thinking is always thinking, but philosophical thinking is, upon the whole, at the extreme end of the scale of distance from the active urgency of concrete situations. It is because of this fact that neglect of context is the besetting fallacy of philosophical thought.⁴³

In the first edition of Quine’s *Philosophy of Logic*, the first page contains the remark: ‘I would say that a sentence is logically true if all sentences with its grammatical structure are true.’⁴⁴ Sixteen years later, in the second edition, that sentence had been removed. But what is intriguing is that such a sentence could ever have been written by a respected philosopher. It means that the left hemisphere’s rule-following is allowed to have the status of truth (a certain kind of truth, at least). This is exactly what the left hemisphere believes: that it is cold in tropical Ecuador, because that’s what the logical structure – though starting from a false premise – dictates. But what kind of truth is that, and why would we be right to pursue it?

PRECISION VS ACCURACY

Earlier I made a distinction between precision, which literally means cutting something off too soon, and accuracy, the literal meaning of which is to exhibit due care towards the subject of concern. Rationality, the left hemisphere's version of reason, demands we be precise, otherwise (so it believes) meaning will escape. Thus philosophy has taken to mimicking science.⁴⁵ Yet meaning is not increased – more often diminished – by the process, and all that is achieved is a lack of flexibility. There is a kind and a degree of reaching after precision, clarity and rigour which is misplaced, because its subject becomes more and more tenuous as this process continues. It ends in a kind of increasingly unrewarding pedantry, reminiscent of an anorexic's attempt to split a pea rather than swallow it. The attempt is to *over-clarify* an area that intrinsically does not permit it. 'It is the mark of an educated man', wrote Aristotle, 'to look for precision in each class of things just so far as the nature of the subject admits'.⁴⁶

Human affairs are a case in point. Knowledge of something that is by its nature not precise will *itself* have to be imprecise, if it is to be accurate. Aristotle again: 'For when the thing is indefinite the rule also is indefinite ... the decree is adapted to the facts.'⁴⁷ In the same vein, Whitehead writes:

There is a conventional view of experience, never admitted when explicitly challenged, but persistently lurking in the tacit presuppositions. This view conceives conscious experience as a clear-cut knowledge of clear-cut items with clear-cut connections with each other. This is the conception of a trim, tidy, finite experience uniformly illuminated. No notion could be further from the truth.⁴⁸

Contrary to some fashionable philosophers, and not just those of the 'Continental' tradition, I agree with Ortega y Gasset that 'in philosophy, clarity is courtesy'. We do have a duty, to ourselves and to our interlocutors, to be as clear as our subject of enquiry permits – *but not a whit more*. When we trespass further, we blunder: we substitute something petty for something great. According to Edmund Burke, 'it is the nature of all

greatness not to be exact'.⁴⁹ His point is that precision is narrow in its focus: it deracinates and simplifies to achieve its effect. It cannot accommodate what lies beyond precision. 'A clear idea', he concluded, 'is therefore another name for a little idea.'⁵⁰

No-one expressed the proper relationship between precise thinking and missing the point better than Pascal. He contrasts what he calls *les esprits fins* ('subtle spirits') with 'geometers': what makes 'geometers' incapable of subtlety, he says, is that

they do not see what is there in front of them, and, being used to the crude, cut and dried principles of geometry, and to never reasoning until they are certain of their principles, they're lost when it comes to the subtleties, where you can't lay your hands on the principles in this way. Such principles are scarcely to be seen at all; they are sensed rather than seen; it is well-nigh impossible to get anyone to understand them if they do not sense them for themselves. They are so fine and so numerous that you must have a very delicate and very acute sense to perceive them, and without for the most part being able to demonstrate them in sequence, as one would in geometry, because such principles are not to be had, and because there would be no end to such an undertaking. You've got to see it just like that, at one glance, and (at least to a degree) without going through any reasoning process. So it is rare that the geometers achieve subtlety and that subtle minds are geometric, because the geometers want to treat matters of intuition like geometric proofs, and make fools of themselves, wanting to start with definitions and then move on to principles, which is not the way to deal with this kind of reasoning. Not that the mind does not do so, but it does it implicitly, naturally, and without artifice; for it is beyond man's wit to say how, and even to intuit it belongs only to a few.⁵¹

The lust for precision comes from a need for certainty. However, knowledge not only does not imply certainty, but is actually incompatible with certainty. Certainty resides only in our concepts, not in the reality to which we apply them. There is an intrinsic tension for the philosopher between the rational pursuit of certainty and the rational desire for

knowledge. As Hegel pointed out, ‘immediacy’ (the quality of being understandable without the need for any other concept or idea) is not compatible with determinacy, and hence certainty is purchased at the expense of content: in Scruton’s phrase, paraphrasing Hegel, ‘the more certain our knowledge the less we know’.⁵² In a similar vein, Claude Lévi-Strauss wrote that:

the work of the painter, the poet or the musician, the myths and symbols of the savage, ought to be seen by us, if not as a superior form of knowledge, at least as the most fundamental, and the only kind really common to us all – knowledge of which scientific thought is merely the sharpened point: more penetrating because it has been honed on the stone of fact, but *at the price of a loss of substance* ...⁵³

The left hemisphere’s experience is precise but diminished and fragmentary, taken out of the flow of experiential life; in fact, tending towards stasis.

The harm done by precision is that it limits what we find in reality. The right hemisphere is conventionally said to have ‘coarse’ semantic coding (I am always amused by that – such a revealingly loaded word), whereas there is nothing coarse about the left hemisphere, with its ‘fine’ (another loaded word, when you think about it) semantic coding. What this means is that the left hemisphere narrows down to a highly localised network and hence to a local, usual and familiar set of associations. This is not always bad – it renders us important service in the day-to-day world. But it is a hopeless way to embark on an understanding of the complexities of reality. The right hemisphere activation is at the same time more provisional, less prepotent, than that of the left hemisphere, and more diffuse, engaging a much broader semantic field, including elements only distantly related.⁵⁴ The point to understand here is this: the *less* sharply each word’s meaning is specified, the *more* likely it is to connect to other words and concepts. Needless to say, this makes the right hemisphere invaluable in enabling us to understand a range of implications,⁵⁵ to see the overall ‘point’,⁵⁶ to understand all that is non-literal in language,⁵⁷ and to gain insight into an interrelated whole.

Words constantly shift in meaning, and it is only the ‘wobble-room’ in language that enables it to keep true to what it purports to describe. ‘Just as a good swimmer must be able to swim up-stream, so the philosopher should master the unspeakably difficult art of thinking up-speech, against the current of clichés’, wrote the philosopher Friedrich Waismann, a pupil of Wittgenstein:

Language is an instrument that must, as occasion requires, be bent to one’s purpose. To stick to language as it is can only lead to a sort of Philistinism which insists on the observance of the *cliché* and will end up with a hara-kiri of living thought ... Correctness is a useful, but a negative virtue.⁵⁸

As Bryan Magee points out, the demand that one define one’s terms in advance is not only limiting to thought, but actually illogical:

the clinging notion that if we are to have a worthwhile discussion we need first to define our terms is demonstrably self-contradictory. Every time we define a term we have to introduce at least one new term into the definition, otherwise the definition is circular. But then we are under an obligation to define our new term. And so we are launched into an infinite regress. Attempts to clarify all our terms must, and can only, result in discussions of words and meanings to which it is logically impossible there should ever be a conclusion. So discussion, if it is to take place at all, has no alternative but to make use of undefined terms.⁵⁹

The hunger for certainty leads to a quest for precision where precision is actually harmful. When dealing with complex conscious beings rather than machines, there can even be a sort of slovenliness about certainty. To quote a not uncritical obituary of Sir Leslie Stephen, the founding editor of the *Dictionary of National Biography*,

To love certainty overmuch is often to be content with too easy solutions, and definiteness may be achieved only at the price of inadequacy ... For, after all, neither literature nor life is quite sane

and orderly, and the whole truth, perhaps the most vital part of the truth, is not to be looked for in a clear and well-regulated survey. A thing may be perfect only because it is incomplete ...⁶⁰

This, too, is a point made by Waismann:

There is nothing like clear thinking to protect one from making discoveries. It is all very well to talk of clarity, but when it becomes an obsession it is liable to nip the living thought in the bud. This, I am afraid, is one of the deplorable results of logical positivism, not foreseen by its founders, but only too striking in some of its followers. Look at these people, gripped by a clarity neurosis, haunted by fear, tongue-tied, asking themselves continually, 'Oh dear, now does this make perfectly good sense?'... some of the greatest discoveries have even emerged from a sort of primordial fog. (Something to be said for the fog. For my part, I've always suspected that clarity is the last refuge of those who have nothing to say.)⁶¹

Waismann, it should be remembered, was a member of the notoriously 'rigorous' Vienna Circle, himself one of the key theorists in logical positivism, a mathematician and a physicist, and Reader in the Philosophy of Science at Oxford.

There is an important role for ambiguity (polysemy) in all understanding, something which metaphor, symbol, humour, tone of voice, and all the implicit modes of expression of the arts best understood by the right hemisphere, imply. This is not ambiguity in the sense of just not having taken proper trouble to pin down the meaning: but in the sense of having, indeed, taken proper trouble *not* to pin down the meaning too closely, so as to let it live – the proper rigour of ambiguity.⁶² Bringing an unwarranted simplicity to the matter strips away layers of depth, rather than enhancing insight.

Everything is in truth a matter of degree, and everything changes with context – all of which the 'take' of the right hemisphere accommodates better than the left. And the characteristic approach of the right hemisphere is better designed to respect uniqueness. Our ability to produce and

understand generalities was developed and directed to cope with practical requirements; it relates to our tendency to classify our surroundings in a manner that will ensure useful action. All actually existing entities, being unique, can conform only partially to the categories to which our minds consign them; and everything is what it is only within the context in which it finds itself. But the left hemisphere privileges categories in order to make general predictions; thus matters of degree, context and uniqueness are sheared away when the left hemisphere's rationality takes over from the right hemisphere's reason. The process is reminiscent of an attempt to preserve a dragonfly by squashing it into a matchbox.

The dangers of removing things from context apply not just to the more particular case of rendering explicit and precise something whose whole *existence* depends on being implicit and unstated – such as remarks that are humorous or ironic, words that are metaphorical or poetic – but to our simplest categorisations. The most everyday words require to be seen in context, and to understand them clearly they cannot be abstracted from that context.

Take something measurable, like the size of a cereal carton. We may be able to say that it is large, without having to measure it. Our decision is contextual. But, if we agree it is large, could it also be small? Apparently so. In the US there are four sizes of cereal packets: 'jumbo', which means very large; 'economy', which means large; 'family', which means medium; and finally 'large', which means small. (In other words it may be compared with either an absolute or a relative standard.)

The left hemisphere has more of an affinity for what is general than what is unique, and hence is keen to develop rules for putting things in categories where they can be managed. It does so based on the presence or absence of a single feature. But classifying is not stable when based on a single feature, precisely because it ignores context. Thus, a chihuahua is a dog, and, unsurprisingly, a skinny chihuahua is a skinny dog, and a yellow chihuahua is a yellow dog. But a tall chihuahua is not a tall dog. More interesting is the so-called 'pet fish problem'. A guppy is neither a typical pet (think dog), nor a typical fish (think salmon). But a guppy *is* a typical pet fish: here two contexts are required to overlap in order to make the statement true.⁶³

We need to categorise in order to make sense of experience. This makes experience neat and orderly – easy to deal with. Surely precision about our

categories can only help here? Since neither hemisphere can begin wholly afresh with every encounter, categorisation is not just a left hemisphere business. But it takes place differently in the two hemispheres, in keeping with their proclivities to focus on a detail or on the whole picture. This is why in the left hemisphere it tends to be carried out according to the presence or absence of a certain feature. For example, employees of a company are those on its payroll. That is nice and precise. But are the owner of the company, who acts as managing director, and the company lawyers, who are all on the payroll, employees? The distinguishing feature of birds is that they fly around; but the kiwi, that doesn't, is nonetheless a bird.

In the right hemisphere, categorisation tends to be carried out according to the degree to which the object, taken as a whole resembles an exemplar – employing what Wittgenstein called a 'family resemblance'. There is no one feature the possession of which decides the case; the secret is pattern recognition. Here it might be easier (though not always) to see that there is something else that goes to making someone an employee, and that the MD and the company lawyers don't have it; or there is something else that goes to making a bird that a kiwi does have. This hemisphere difference, providing two modes of categorisation, one precise and according to detail, the other more global and according to exemplars, must have considerable survival value, as it is also present in other species – including kiwis and guppies.⁶⁴

Sometimes the left hemisphere's precise, 'either/or', criterion is more helpful. For example, there are precise criteria for being a grandmother, namely that you are a woman whose child has become a parent. Here the exemplar of a grandmother – a wise, elderly, white-haired, woman – gets some grandmothers, certainly, but takes in some old women who never had children, and fails to identify the young fitness fanatic with long blonde hair, who has a grandchild. On the other hand, possession of a steeple, while it catches many churches, fails to catch those churches which don't have a steeple, and falsely identifies those buildings, such as a huge and bizarrely unattractive office block in West Oxford, and a parking structure at Baylor University, Texas, that do. There is no single feature to identify a church that will be as helpful as the family resemblance approach. We need both.

In terms of the law, it is usually helpful to apply left hemisphere categorisation at some points – 'for this matter to qualify as an X, it must

have a y' – but it will also be necessary to look at past cases, effectively employing the 'exemplar' approach of the right hemisphere, and be able to say, this case is more like case A, than case B, overall. The right hemisphere is more flexible, and so is this process.

It seems to me that one of the most distinctive human characteristics is that of flexibility. 'Single-mindedness is all very well in cows or baboons', wrote Aldous Huxley: 'in an animal claiming to belong to the same species as Shakespeare it is simply disgraceful'.⁶⁵ Shakespeare was, according to Coleridge, 'myriad-minded': his genius was manifest in the unpredictable freshness of his creations, who often refuse to respect the stereotype the plot demands of them.⁶⁶

To those who like regularity (literally, 'the following of rules'), another trait prominent in autism, such flexibility and originality can seem no more than inconsistency. Richard Duppa, a lawyer and draughtsman, observed drily: 'While philosophers were seeking to find a character for man to distinguish him from other animals, inconsistency ought not to have been forgotten.'⁶⁷ Whether he approved or not, I don't know: he had a good sense of humour. However you look at it, consistency has its unacknowledged dark side: 'Too much consistency is seeing situations as similar when they are, in fact, different', as John Kay puts it, and as I have tried to suggest.⁶⁸ Or, to quote Aldous Huxley again:

Too much consistency is as bad for the mind as it is for the body. Consistency is contrary to nature, contrary to life. The only completely consistent people are the dead.⁶⁹

The need for consistency and certainty drives out ambiguity. Philosophy literally means the love of wisdom; and wisdom, as the pronouncements of the Delphian oracle demonstrated, is never void of ambiguity. One of the most justly famous works of literary criticism is entitled *Seven Types of Ambiguity*: different types of ambiguity account for much of the richness and depth of literature. As its author William Empson put it, in the work of art you have something like a stew, in which the pieces of meat you recognise play a part, but 'the juice in which they are sustained must be regarded with a peculiar respect because they are all in there too, somehow, and one does not know how they are combined or held in suspension.'⁷⁰

Here we are close to what Keats, in a well-known passage in one of his letters, called ‘negative capability’:

at once it struck me what quality went to form a Man of Achievement, especially in Literature, and which Shakespeare possessed so enormously – I mean Negative Capability, that is, when a man is capable of being in uncertainties, mysteries, doubts, without any irritable reaching after fact and reason.⁷¹

It is because of the complexity of truth that we need to reach down into the realm of the unconscious, not just into that tiny part of our embodied being of which we are fully conscious, and where all is clear. The painter and sculptor Braque said that ‘in art there is only one thing that matters: what cannot be explained.’⁷² It is the duty of art not to let things collapse into an illusory simplicity, but to permit them to be present as far as possible in all their complex and sometimes contradictory nature, something that can be achieved only by allowing much to remain implicit.

Clarity is a wonderful, indeed beautiful, thing, where it can be achieved without loss of truth. We cannot let ourselves off the hook of striving for it. But we need also to know the proper place to stop. Its application is limited, and on a larger scale its virtue becomes a vice; then it is no longer the agent of truth, but – somewhat paradoxically – its obfuscator. It gives us the bogus sense that we have covered the ground, whereas we have only started scratching it. As Rabindranath Tagore put it, ‘the small wisdom is like water in a glass: clear, transparent, pure. The great wisdom is like the water in the sea: dark, mysterious, impenetrable.’

It would be a mistake to think that it is just in a somewhat mystical sounding realm that precision causes problems: it can cause them in any philosophical judgment. Here I think of Whitehead once more:

The sharp-cut scientific classifications are essential for scientific method, but they are dangerous for philosophy. Such classification hides the truth that the different modes of natural existence shade off into each other.⁷³

And even at the level of everyday life, precision can be far from helpful. Since our language has relatively few colour words, there will be many shades that might be classified as 'blue' by some people, as 'green' by others, and as 'grey' by still others, without anyone being wrong. But that's not because there is no right or wrong: try calling it 'orange'. Language is neglectful of the unique. We saw that 40 million colours are discriminable by the human eye: if we had 40 million words for colours that would not be an improvement. Language relies on approximation: a language with a word for every distinguishable aspect of the world would not be a language at all. It would be like the map that is the same size as the world it maps.⁷⁴ Language always shrinks reality: the one exception to this is poetry, which absolutely depends on ambiguity to escape. Language is a gross approximation – and that's why it works. Yet there exist people who believe that only once a thing is stated in *language* can it be precise. (Well, I grant you, a map has a precision that life lacks. It's just that that precision has little to do with reality.)

The philosopher Bryan Magee writes that '*whenever* I see, all that language can do is to indicate with the utmost generality and in the broadest and crudest of terms what it is that I see':

Even something as simple and everyday as the sight of a towel dropped on to the bathroom floor is inaccessible to language – and inaccessible to it from many points of view at the same time: no words to describe the shape it has fallen into, no words to describe the degrees of shading in its colours, no words to describe the differentials of shadow in its folds, no words to describe its spatial relationships to all the other objects in the bathroom. I see all these things at once with great precision and definiteness, with clarity and certainty, and in all their complexity. I possess them all wholly and securely in direct experience, and yet I would be totally unable, as would anyone else, to put that experience into words. It is emphatically not the case, then, that 'the world is the world as we describe it', or that I 'experience it through linguistic categories that help to shape the experiences themselves', or that my 'main way of dividing things up is in language' or that my 'concept of reality is a matter of our linguistic categories'.⁷⁵

We *can* find ways of using language and figures to be more precise, but we risk conveying less by doing so. For example, being told that a certain colour is 'bluey-green', though vague, is much more informative than telling me that it has an RAL number of 5018 or a wavelength of 492nm. Similarly, telling me that a certain Thai engineer earns 25,250 baht per month is more precise, but much less helpful, than saying he or she is well-off by Thai standards, though still poor by those of the USA.

Precision may impair the content of an utterance in a number of ways. Thus I may say to a friend who is coming to dinner, 'do please bring your toothbrush' – meaning he is welcome to stay over. But if I am more precise, I enter a mire. 'Please bring your toothbrush and some toothpaste.' Worse – much worse: he may now think I am suggesting that he needs to be prompted to freshen his breath. A broad vague term, doing a lot of work, has suddenly collapsed into too narrow a specificity. I am now obliged to carry on with this process. 'Please bring your toothbrush, toothpaste and some pyjamas' avoids the imputation of bad breath to some extent, but is now in danger of being a comment on my prudishness, or his nudishness, and is getting so specific that it may seem odd that I am not requiring the addition of a hairbrush (perhaps I am implying that he can borrow mine?) or a razor.

In order to be effective, laws have to balance precision with vagueness. It might seem that the more precise the law, the better it is for those who have to obey and to enforce it. But clearly this is not always – indeed not often – the case. Let's take a very simple case. Where there is a sign stating 'no ball games in the park', a person practising archery there ought not to expect to go ahead with impunity simply because the projectile in this case is not a ball. Equally, someone playing a handheld plastic pinball game would not expect to be apprehended for playing this particular 'ball game' in the park. But to specify all proscribed projectiles, along with exceptions to the list, would be unbearably tedious, would require the environment to be even more polluted with signs, and much bigger signs at that, than it already is, and would convey much less information, because few people would have the patience to read them: the funeral of common sense.⁷⁶ The proliferation of prosperous lawyers *pari passu* with the proliferation of laws suggests that there must always be a large element of interpretation in any system, however detailed its provision.

And its very specificity would be a strong argument that anything not specifically mentioned was permissible, even if potentially lethal. The more you pursue this path, the more you are open to the burden of completeness. There will always be such items, even if only because they were invented, or the term came into parlance, after the notice was last revised (and the notices would have to be endlessly revised). And how stupid do you have to assume your reader to be? Exhaustiveness is exhausting, and exhausts the human in us. What do you assume he cannot work out for himself? The concept of an appeal to reasonableness still, just, lingers on in the courthouse, so that we expect the law to be interpreted flexibly, with a sense of proportion and, dare I say it, a proper sense of the absurd, not imposed by administering a machine-like algorithm. Soon we may not be so lucky. As Louis de Bonald saw in the first few years following the French Revolution : ‘A people that has been deprived of its customs through a desire for written laws has imposed on itself the harsh necessity of writing down everything, even its customs.’⁷⁷

Occasionally, it seems to me, we need to abide by the letter of the law, particularly where a reasonable person could have so interpreted it, and particularly where to do so gives the benefit of the doubt to a defendant; but mostly we hope that the spirit of the law may prevail over the letter.

There are borderline cases. Personal judgments are inevitable in the law, as they are in medicine, in both of which the whole experience and personality of the decider may influence judgments of what is reasonable, effective or humane. That judges differ, provided it is within an unspecifiable, though recognisable, circumscribed span, is not a matter for regret, but for acceptance, perhaps even celebration; and indeed a variety of approaches is truer to the range of views on such matters held in a society than just one, inflexible, view ever could be.

A failure to see this leads to accusations of unfairness when sentences for similar offences differ. There are calls for standardisation. But the alternative is to have inflexible sameness in every case, resulting in (justified) accusations that ‘the law is an ass’, because common sense was unable to discriminate differences in the apparently similar cases. Equally, where a health authority may choose its priorities by reference to the needs of its particular population, this leads to accusations of a ‘postcode lottery’, because services available in one area are not in another; but where it no

longer has such freedom to choose, the accusation is that central planning of healthcare ignores local needs and local preferences.

Additionally, what was considered reasonable – or offensive – 50 years ago, might not be so considered today. This is not grounds for considering that judgment cannot work, but that we clearly cannot work without judgment. These are *necessarily* vague areas. Even some that look superficially precise, and where our language is precise, may be rendered ‘open-textured’, in Waismann’s phrase, by the onward march of technology. Thus, ‘mother’ is a classically precise term; but now that a baby may be derived from the ovum of one woman, delivered from the womb of a second woman and brought up by a third, the term has become ‘porous’ to a degree that renders precision impossible, at least without some such ugly qualifier as ‘genetic’ mother, ‘birth’ mother or ‘care’ mother.

By being more precise we increase the risk of spurious inaccuracy – being perhaps trivially wrong. ‘A bunch of kids’ is more accurate than ‘seven’ if there were in fact eight. Dryden died in 1700: if I say he died at the beginning of the eighteenth century, I am right even if I am thinking of 1704, whereas if I say he died in 1701, I am less mistaken, but plain wrong. Vagueness can be importantly protective. If I tell you that a fungus you have picked is an *amanita*, you will probably not want to eat it, and will live; if, being more precise, I tell you it is *amanita caesarea*, a prized delicacy, and it is in fact *amanita phalloides*, otherwise known as deathcap, you may not.

Sometimes it is in the nature of our *knowledge of the object* that we cannot be precise, as with the 9,000,000 year-old dinosaur; and sometimes in the nature of *the object of our knowledge*, since in real life things tend to spread, blur and ramify: rivers and streams, woods and forests, hills and dales, families and communities are all like this.

We have seen already how bogus precision creeps into the ‘mismeasure’ of all things human, not always because, as Gould thought, they simply can’t be measured (though many can’t), but because norms cannot have clear cut-off points. The problem is not that we cannot measure obesity, for example; we can, at least with a non-negligible degree of accuracy. But behind our measurements lies an inevitably arbitrary, but sharp, boundary: obese or not. Therein lies the problem, or at least one of them.

CALCULATION VS JUDGMENT

Our admiration for calculation deserves scrutiny. But first let me say something about precise calculation and brain lateralisation.

There is considerable overlap between areas involved in calculation and those involved in language.⁷⁸ This is because doing arithmetic involves elements that are obviously linguistic. Being able to recite and articulate number names and ‘times tables’ involved in multiplication draws on language areas of the left hemisphere.⁷⁹ However, there are just as obviously non-linguistic elements, including the visual representation of number forms and relationships, which draw on both hemispheres.

Exact calculation shows a more left-lateralised pattern of activity than approximate calculation.⁸⁰ Approximate calculation sounds like something obviously inferior, but by ‘approximate’ calculation is meant, for example, being able to see which of two proposed answers to a problem, neither of which is precisely correct, is *closer* to being correct. This does not involve carrying out a sequence of verbalising processes according to rules, but having a ‘feel’ of what the right answer is likely to be. Even just identifying which of two numbers is the larger has been found to exhibit a right hemisphere lateralisation, as opposed to the strong left hemisphere lateralisation involved in multiplication.⁸¹ It is not perhaps surprising that understanding false versus genuine facial expressions of emotion, whether the task is deliberate or automatic, depends on the right orbitofrontal cortex and temporoparietal region.⁸² But so does number processing. In a task involving appreciating the relative value of a number

the same parietal functional asymmetry seems to underlie both automatic and intentional numerical processing with only the right, but not left, intraparietal sulcus being causally relevant for successful performance during both tasks.⁸³

There is I believe, a suggestive comparison here with hemispheric contributions to language. Most aspects of syntax, certainly syntax that is in any way complex, are far better carried out by the left hemisphere;

however, understanding ultimately what an utterance *means* is highly dependent on the right hemisphere's so-called 'pragmatics'.⁸⁴

The quantification of human variables is almost bound to entail measuring a proxy that is quite different from what it purports to be measuring, and coming up with a figure that implies a degree of precision neither the subject, nor the means of measurement, can sustain. This is not an amusing technicality: it happens every day and plagues our lives.

In an era in which measurement and monitoring apply across the board they can have a baleful effect on creativity. In September 2016, the Arts Council of England forged ahead with plans to impose a standardised system for measuring artistic quality on its 'National Portfolio Organisations'. Arts organisations themselves were understandably sceptical of a standardised approach to measuring quality in the area of creativity, not to mention the administrative burden associated with it. Despite resistance the Arts Council chugged on regardless, claiming to have developed a 'meaningful measure' of artistic quality that yielded consistent results, and providing a digital 'platform', ominously called Culture Counts, to manage the process and handle the data. You can tell how much the administrators of the Arts Council understand about art from their beautifully crafted statement that 'the trial has given us confidence that there is sufficient support within the sector to examine the quality of work in an exciting, contemporary way, enabling us to now support a wider roll out of the quality metrics'. Shelley could not have put it better; indeed he would have been rendered temporarily aphasic. One 'arts professional', whatever that is, possibly speaking for many, is reported as expressing concerns about 'reducing artistic quality to a statistic'.⁸⁵ Also to something that has to be delivered in measurable amounts within a time schedule. If that's what 'the public requires' when it comes to the spending of public money, the public needs to be educated. Wherever money comes from to support the arts, the only way that makes sense – as with research in academe – is to choose good people by judgment rather than by formula, and let them get on with it, not hover over them, brandishing a metric, and breathing down their necks.

One of my favourite lines is 'OK, the data's lousy, but it's all we've got': according to a booklet bearing this title, it is 'an actual quote, and the speaker, a full professor of economics at a reputable US university, is reasonably well known'.⁸⁶ As the booklet's author, Gerald Gill, points out,

‘it may seem obvious, but in view of what has just been said it is perhaps worth stating the obvious: *wrong data are worse than no data*’. And he quotes the biologist and historian Robert Chambers’ critique of ‘survey slavery’:

Exhausted researchers ... stare at print-outs and tables. Under pressure for ‘findings’, they take figures as facts. They have neither time nor inclination to reflect that these are aggregates of what has emerged from fallible programming of fallible punching of fallible coding of responses which are what investigators wrote down as their interpretation of their instructions as to how they were to write down what they believed respondents said to them, which was only what respondents were prepared to say to them in reply to the investigators’ rendering of their understanding of a question and the respondent’s understanding of the way they asked it; always assuming that an interview took place at all and that the answers were not more congenially compiled under a tree or in a teashop or bar, without the tiresome complication of a respondent.⁸⁷

In mathematics – at least in calculation, which is just one part of mathematics – precision may seem to be essential. For some purposes, naturally, it is: our society’s exchange mechanisms depend on precise calculation, as does engineering, and as do many elements of science. But it is quite a jump from such a utilitarian justification of calculation to the wider belief that any conclusion reached by the exercise of reason can be truly rational only through the deployment of calculation. Yet that, it seems, is a view increasingly held, explicitly or otherwise, in the contemporary world. And it involves (indeed it requires) the transposition of what the right hemisphere identifies as ‘quality’ into what the left hemisphere can manipulate as ‘quantity’ – that’s to say, the conversion of something imprecise into something precise – a number – the necessary precondition for calculation to proceed. Much harm ensues.

From the point of view of the hemisphere hypothesis, numbers are interesting in their own right. We have, alas, become used to trying to represent quality by quantity, but not to seeing that quantities, too, have quality. By this I mean three things.

First, numbers themselves have qualities – certainly the lowest numbers, from 1 to 10 do, and to a mathematician many more, such as, in particular, 37 or 1729. They differ not just in amount, but in the characteristics of the number. Each of the first numbers, 1–9, has a different role and appears in different places for different purposes throughout nature – odd numbers, like asymmetry, being particularly associated with generating newness – and has different qualities within music.⁸⁸ According to Jung,

There is something peculiar, one might even say mysterious, about numbers. They have never been entirely robbed of their numinous aura ... Unlike concepts, they are based not on any psychic conditions, but on the quality of being themselves, on a “so-ness” that cannot be expressed by an intellectual concept. Under these conditions they might easily be endowed with qualities that have still to be discovered. I must confess that I incline to the view that numbers were as much found as invented, and that in consequence they possess a relative autonomy analogous to that of the archetypes.⁸⁹

Like everything else, numbers can be approached in the typical mode of the left hemisphere, or of the right. In left hemisphere mode, they are thought of as absolute entities, abstract, of equal quality, and adynamic (the word ‘statistics’ is derived from the same root as ‘static’). In right hemisphere mode, they may be seen as dynamic relations: music and beauty arise out of the relational nature of numbers, their proportions and structures. In music this is inherent in melody, harmony and rhythm. Something as simple as changing from 4/4 time to 3/4 time changes the *quality* of the experience entirely, and of course harmony and melody are utterly changed in their meaning by altering the relationship between the notes – in which the music exists, and in which alone it exists – even by small (though not by infinitesimally small) amounts, such as a semitone or a quartertone.

In the visual world certain proportions, such as the Golden Ratio (ϕ) which is found repeatedly in nature, are experienced as intrinsically beautiful.⁹⁰ Thus the number has human meaning. The golden ratio is arrived at mathematically by taking any number you like, dividing 1 by it,

adding 1, and repeating the process an infinite number of times. Whatever number you start with, you converge on a number that is approximately 1.618, universally appreciated as aesthetically satisfying in its relation to the number one. I say ‘approximately’ because, like other important ratios we find everywhere in nature, such as π , e , and $\sqrt{2}$, it can only be approximated, never finally reached. It is said to be ‘irrational’: that is, its inherent reality can, in the nature of things, be specified only imprecisely.

Thinking again of numbers as having individual properties, the golden ratio has a relation with the number 5, since ϕ is repeated throughout the structure of a pentagon and a pentagram, but that relationship is concealed.

The idea that numbers are relational, rather than absolute, is also embodied in colours: colours have frequencies, and those whose frequencies do not ‘harmonise’ are said to ‘clash’. For Pythagoras, there was a natural harmony in the universe founded on numerical relationships, and it was expressed as the music of the spheres, a belief that the numerical proportions – the relationships – of planetary movements expressed a music inaudible to our ears, a belief that was held up to at least the time of Johannes Kepler, who wrote a treatise on the subject, *Harmonices mundi*. Shakespeare’s Lorenzo in the *Merchant of Venice* puts it thus:

There’s not the smallest orb which thou behold’st
But in his motion like an angel sings,
Still quiring to the young-eyed cherubins;
Such harmony is in immortal souls;
But whilst this muddy vesture of decay
Doth grossly close it in, we cannot hear it.

I mentioned Jedediah Buxton in Chapter 9. He was an extreme case of the apprehension of quantity dominating the apprehension of quality, and of meaning, to the point of the latter’s total obliteration. But it is only an extreme case of a much more common phenomenon in contemporary culture: the attempt to convert as much as possible of what we value qualitatively into a quantity that can be subject to an exercise in calculation and ignore, Buxton-like, anything that cannot be converted. Very often these are all the most important things.

This is the second sense in which quantification introduces qualities of its own. I have seen a 300-page report on the impact of a certain projected

development on a region of outstanding natural beauty that catalogued possible impacts on the local economy, employment, the return on investors' capital, the likely productivity of the scheme, its potential for 'recreational activities' and so on, and only on the last page acknowledged that there were 'possible impacts' on the profound beauty, peace and majesty (naturally the terms are not theirs, but mine) of the landscape, but that these were impossible to assess and had therefore not been included in the calculations. Even more striking is a report from the World Bank on the World Health Organization's onchocerciasis control programme, which saved hundreds of thousands of poor people in Africa from going blind. A cost-benefit analysis was 'inconclusive' because the people were so poor that saving their eyesight had little economic impact. 'There are humanitarian benefits associated with reducing the blindness and suffering caused by onchocerciasis', they conceded, but 'these benefits are inherently unmeasurable, and we will not account for them here.'⁹¹

Our desire to calculate leads us to invent weights and measures to 'evaluate' issues before us. But numbers can never *evaluate* anything at all, precisely because they don't deal with values. Even if you 'evaluate' something as 'profitable', the value is nowhere to be found in your measurement, which has no capacity to deal with value (although, subtly, it imports a pernicious value, that of the person who believes everything can be measured). The value is what is in the background here: your desire to make a lot of money. When we measure the worth of a person, a poem, a quartet, a painting or a landscape – or a social policy – it is not that *they* are judged by our measures, but that the appropriateness of our measures is weighed in the balance by *them*, and most often found wanting.

And then there is the third point, that quantity in and of itself changes quality. For example, we casually say 'you can't have too much of a good thing'. Yet more of a good thing – say, liberty, transparency, equality, pudding size, hang-gliding, insulation, economic growth, safety, hygiene – does not inevitably make things better: it often makes things worse. Even things we think of as bad – say, punishment, secrecy, kale salads, shame, hunger, discomfort, constraint, taxation, grief – don't get better if diminished beyond a certain point. *Quantity always changes quality*. This is so obvious that I am sorry to have to state it, but the fact remains that in public debate, the very large majority of the time, some things are just assumed to be better, the more we get, and others to be simply bad, however

much we have, and to be extirpated root and branch. If you asked people to consider whether this was realistic they would probably say ‘no’, but would then go back to behaving as if it were true. ‘Complete inability to control the response to pain is damaging’, writes John Kay, ‘but so is too much control.’⁹² For *everything* there is an optimal amount, and it is rarely if ever zero or infinity. Even what appears evil may cause some good, and what seems good cause some harm. If it is true that every devil has his angel, it is also true that every angel has his devil (see Plate 24).

Furthermore, some things cannot be expanded indefinitely without radically changing their nature. To take an obvious example, access to wild and beautiful places: once they are mass tourist destinations they are no longer wild and beautiful, so the process of expansion destroys the reason for their being desirable. No doubt controversially, I would argue that this can happen with university education: the attempt to expand it beyond a certain level begins to erode the valuable things for which it was desirable in the first place. Of course it remains an open question, for each of these issues, *at what point* we start to go down the other side of the curve, something on which reasonable people may differ, but it is a question that is insufficiently publicly discussed. It is simply assumed that there is a straight line. I shall come back to our predilection for linearity.

Ultimately, many human qualities are just not quantifiable in any but the vaguest conceivable way, yet we know exactly when, and to a large degree how greatly, we experience them: for example, beauty, anger, hunger. Asking to quantify them would be like someone hearing Othello’s great howl of rage and despair, ‘O Spartan dog, more fell than anguish, hunger or the sea!’, and responding: ‘Yes, OK – but how much more fell?’

I will have more to say about morality in due course, but since we are here talking about the drive to quantification, I wish simply to note that it surely says much about us as a society that serious moral philosophers now believe there is a calculus of morality, whereby we can tot up the costs and benefits, and come up with an answer. This is the fulfilment of Leibniz’s dream of his famous abacus, and declaration *calculemus* (‘let us calculate’). Thus we have the infamous ‘trolley’ thought experiments: would you be doing the morally superior thing if you pushed a fat man off a bridge in such a way that in landing he switched the points, and changed the course of a runaway truck, so that it would kill only one adult and two children instead of five adults?

No doubt it would be said to be in the service of our friend, objectivity. Yet one of the reasons we are captivated by great plays such as *Richard III* – to return to the Jedediah Buxton example – and novels, narratives and myths, is that they allow us to stand back: to step away from the immediacy of experience, through what I call ‘necessary distance’, and see the complexities under which all human life labours. Such distance does not alienate, but, on the contrary, enables us to see ourselves with heightened awareness, and to empathise with those who stand *for* us – and for more than us. Great dramatic performances play out, in archetypal form, the intricacies of all human relationships and human motives, the conflicting demands of many-faceted love, of friendships, family and kin, of valued work, vocation, and the urge to create, the striving to preserve dignity and pride, and the lure of beauty towards things that are perhaps exciting, dangerous, deeply fulfilling and unendurable at once – not to mention loyalties to religious conviction, to a society’s cohesion, to the need to avoid pain, and the call to confront evil, to belong to a society and to be a unique individual, to heal, to save and to give meaning to life. In short, they inculcate the practice of judgment. That something like this can be reduced to calculation is an extraordinary idea, to say the least. Here is Roger Scruton:

When Anna Karenina asks herself whether it is right to leave Karenin and to set up house with Vronsky, she is asking herself which of two courses of action would be better. But although she is making a comparative judgment, it is not one that can be resolved by a calculation. She is torn between her obligations to her husband and her child, and her love for Vronsky. Her dilemma is not detachable from its peculiar circumstances – her husband’s vindictiveness and coldness of heart, her son’s sweet devotion, Vronsky’s *Leichtsinn* and Anna’s knowledge of his faults. Dilemmas of this kind exist because we are bound to each other by obligations and attachments, and one way of being a bad person is to think they can be resolved by moral arithmetic. Suppose Anna were to reason that it is better to satisfy two healthy young people and frustrate one old one, than to satisfy one old person and frustrate two young ones, by a factor of 2.5 to 1, ergo I am leaving. What would we think, then, of her moral seriousness?⁹³

The very act of calculation here betrays a lack of awareness of what the whole experience of morality involves. In real life, *of course*, people do not make moral judgments like this, and only a very odd mind – perhaps brilliant at calculation, but otherwise incapable of understanding the richness of the normal human being's world – would think that they ought. If humans ever did, it would be the most grievous folly, one which would spell the reduction of human beings to the status of machines. Calculation works only if you strip humanity to the bone: and then it is no longer human.

More commonly what happens is that we delude ourselves when we retrospect on how we reach moral decisions, much as we are deluded when we retrospect on our motives for many actions, by the fact that when we do so consciously we engage the serial, analytic processing of the left hemisphere. The left hemisphere is a great 'confabulator', as we saw; when it doesn't know, which is much of the time, it doesn't say so: it makes something up to fill the gap. Not being aware of how the decisions were reached, it asserts confidently that we got there by the serial analytic processes it would have used if it had to set out explicitly to tackle the problem. Some professional philosophers then appear to believe this to be the case.

We do not 'work out' moral principles on the basis of utility, as the left hemisphere imagines. Except in artificially contrived situations, such as academic debate, moral decisions are not the product of deliberative calculation, but of unconscious and intuitive judgments, derived from experience and deeply bound up with our emotional sensitivity to others. But they are no less rational for that.

It is a point Waismann makes when rescuing the concept of reason from those who would restrict the term to the left hemisphere's narrower concept of rationality, the exercise of precision, calculation and deduction. 'When the judge reaches a decision', writes Waismann, 'this may be, and in fact often is, a rational result',

yet not one obtained by deduction; it does not simply follow from such-and-such: what is required is insight, judgment. Now, in arriving at a verdict, you are like a judge in this that you are not carrying out a number of formal logical steps: you have to use discernment, eg to descry the pivotal point. Considerations such as

these make us see what is already apparent in the use of 'rational', that this term has a wider range of application than what can be established deductively. To say that an argument can be rational and yet not deductive is not a sort of contradiction as it would inevitably be in the opposite case, namely, of saying that a deductive argument need not be rational. This alters the whole picture. The point to be emphasised is that *a philosopher may see an important truth and yet be unable to demonstrate it by formal proof. But the fact that his arguments are not logical does nothing to detract from their rationality.*⁹⁴

LINEARITY VS THE *GESTALT*

Calculation is just a specific case of a broader aspect of the left hemisphere's mode of reasoning, namely its attachment to linearity, building up its reasoned re-presentations of reality step by step. Waismann's point is that such a logical mode of reason isn't the only form. There is the other twin, equally rational, where 'a philosopher may see an important truth and yet be unable to demonstrate it by formal proof'. That's to say, the philosopher sees the 'important truth' as a *Gestalt*, the whole as a single totality rather than working his way to it as the end discovery of a linear, causal sequence.

An argument is not a single decontextualised event that must compel a conclusion in anyone, ever, at all. It is just one more piece of evidence to sit with, and be weighed with, many others. If it does not fit with the tendency of everything else one knows, from thinking and from the business of life, it may be wise to doubt it. Equally, there may be many truths to which one cannot climb by one thread, but only by a rope woven of many strands. There is profound wisdom in CS Peirce's remark that

philosophy ought ... to trust rather to the multitude and variety of its arguments than to the conclusiveness of any one. Its reasoning should not form a chain which is no stronger than its weakest link, but a cable whose fibres may be ever so slender, provided they are sufficiently numerous and intimately connected.⁹⁵

Moral evaluation in particular involves, or should involve, moving on from what the left hemisphere sees as a simple causal sequence, step by step, to what the right hemisphere sees as a whole narrative: how the person arrived at those particular circumstances, what was going on in his or her mind at the time, what sort of a person would think or act in that way, whether we would like to live in a world where such people form the majority – in other words, the whole human picture, not the mechanistic part picture: Anna Karenina as a troubled spirit, not a sum to be solved.

In Part I we saw that narrative is not adequately understood by the left hemisphere; and that in schizophrenia, logic has to stand in for narrative as

the factor that attempts to link complex human events, with deleterious consequences. Linear causation is the kind of sequence that the left hemisphere *does* understand. But such reasoning can lead us astray, as one particularly elegant piece of experimental evidence neatly demonstrates. Subjects were presented with two scenarios: in one a woman put poison in a friend's coffee, believing it to be sugar, and her friend died; in the other she put sugar in her friend's coffee, believing it to be poison, and the friend lived. In the normal situation subjects naturally judged the second scenario morally worse, as most of us would, because the woman was intent on murder, not the victim of a mistake. However, with the right temporoparietal junction experimentally suppressed using TMS, subjects, relying on their left hemisphere, judged the woman in the first scenario to have acted more immorally, because the friend died.⁹⁶ Here the consequentialist approach, which the left hemisphere adopts, is really to do with an excessive willingness to judge a scenario by the externally observed chain of causation. Causing death is bad: whose action was causally responsible for a death? Then that's the guilty one.

Because the left hemisphere is the hemisphere that believes it *causes* things to happen – it is the manipulator – it privileges the relationship of causation, in which one action causes another. In fact it is claimed by Nikki Marinsek and colleagues that only the left hemisphere infers causation.⁹⁷ Whether that is so or not, the important point is that the right hemisphere is reluctant to assume causation, since the whole person requires the right hemisphere's input for us to judge whether what is taken by the left hemisphere to be causative is *capable of being so construed*. This is a matter of understanding a complex picture as a whole, not just latching on to a single thread. On its own the left hemisphere is over-eager to infer causation, and will infer a causative relationship even where clearly none exists.⁹⁸ The right hemisphere, particularly right temporoparietal regions, is more important for discriminating causation from non-causation.⁹⁹ Whether the proposed causal link is purely physical, as in one ball striking another, or social, as in the fatal coffee cup, the key activations associated with the evaluation are in the right middle/inferior frontal gyrus, right inferior parietal lobule, the right supplementary motor area, and bilateral insulae; for social causal judgments, the right temporo-parietal junction is of critical importance (as the fatal cup experiment demonstrated), as it is involved in judging animacy and intentionality.¹⁰⁰ The right hemisphere's appreciation

of the *Gestalt* is more reasonable, more likely to lead to the truth; the left hemisphere's linear approach is more likely to be mistaken.

And this brings me to another paradox concerning linearity and its limitations. For a rational being it seems obvious that you need to be clear about your goal, and then find the most direct way of pursuing it. To be unclear about your goals, to waste time by not pursuing them by the most direct means possible, is clearly illogical.

Unless, that is, the process doesn't work.

'I think I'll go and meet her', said Alice, for, though the flowers were interesting enough, she felt that it would be far grander to have a talk with a real Queen. 'You can't possibly do that', said the Rose: 'I should advise you to walk the other way.' This sounded nonsense to Alice, so she said nothing, but set off at once towards the Red Queen. To her surprise, she lost sight of her in a moment, and found herself walking in at the front-door again.

To a child this is amusing and nonsensical. However, to an adult – as is invariably the case with Lewis Carroll's paradoxical manner – it reveals a deep truth about the world.

Your ultimate goal might be happiness; and there are worse goals to have. The trouble is that, with all due respect to the US constitution, happiness can't be pursued. People who pursue happiness find that it constantly eludes their grasp, like the bunch of grapes before the outstretched hand of Tantalus. Just as the harder we pursue sleep the more it evades us. Some truths are less self-evident than others (all the true ones, by the way).

There are rational goals that the rational person ought to pursue, which nonetheless can only be achieved by not pursuing them: along with sleep and happiness, these include things as diverse as wisdom, sexual performance, sympathy and being natural. The direct approach destroys its object. Similarly there are things that can be conveyed only indirectly. To recapture the depth of what is said, or in order to say anything truly new, we are always engaged in going beyond everyday language, which means being alert to what is being said *implicitly*. It is because there is so much that cannot be conveyed in any other way, because explicitness changes its nature, that we value – or should value – poetry, humour and embodied

metaphor (otherwise known as ritual) of whatever kind. They all have the same quality that, once they are made explicit or ‘explained’, they completely lose their power and their meaning. Moreover, the difficulty with defining goals and logical methods of achieving them is not *just* that they often can’t be achieved by the direct approach, but that only factors that are not only articulable, but, moreover, have already been articulated, are taken into consideration, leaving out all that is implicit and comes only from engagement with the world and experience of life.

Interestingly, much as the happiest people don’t seek happiness, the wealthiest people are not those who most ruthlessly pursue wealth.¹⁰¹ John Kay cites a number of cases of global giants, household names such as ICI, Boeing, Merck, Pfizer and Citigroup, which were once highly profitable organisations while they focussed on delivering a good product, but which nosedived as soon as the bean-counters took over, and told people to focus on the bottom line – making money. Greed doesn’t pay (although abjuring greed because it pays better to do so is to thwart oneself, since it is the attitude of mind, not a certain action or set of actions, that is both in itself to be desired and goes to create prosperity). Success in business comes, bizarrely enough, as a by-product of running a good business.

Kay might have referred to the case of Kazuo Inamori, a Buddhist priest who took over as chief executive of Japan Airlines in the second half of 2010 at the age of 77, having no experience in the industry. The next year, he returned the company to profit and led it out of bankruptcy. In 2012 he relisted it on the Tokyo stock exchange.¹⁰² His philosophy? Looking after his workers and making sure they enjoy what they do: ‘if you want eggs, take care of the hen. If you bully or kill the hen, it’s not going to work.’ In case you think Japan Airlines was a one-off, Inamori started two companies of his own, the combined market value of which was \$82 billion by 2015.

The problems for the rational mind begin with defining goals. Aims are complex and not infrequently incommensurable – even incompatible, if we are entirely honest. As Kay points out, goals need, in any case, to be flexible, responding to changing circumstances; and these in turn vary depending on *how*, and *why*, we pursue such goals. Since the world is, to all intents and purposes, infinitely complex in its structure, we could not predict it, even if there were no ‘black swan’ events, as Nobel Prize-winning economists have found out, with limited capacity to rescue face from egg.

Some uncertainties are irresoluble, and we do well to recognise our limitations, since it makes for better decision-making. We need to be responsive to each step of the process. If you watch an animal – even an animalcule, such as an amoeba – exploring its environment, you will see it make forays, withdraw and adapt, try again in another direction, withdraw, and then find a direction it is prepared to pursue. Trial and error. Good decision-makers are eclectic and not wedded to ‘consistency’. But when things turn out, for whatever reasons, the way we thought they might, we tend to overestimate *our* role in their doing so. We overestimate our ability to predict and to control. That way disaster often ensues.

An algorithm as a replacement for an embodied skill is one case of an insufficiently flexible path, a concatenation of steps that aims to achieve a reliable goal. At its best, and if the poor performers at whom they are targeted were likely to follow them, they would avoid some poor outcomes. But they would ensure others. They are generalisations, and every case needs to be evaluated on its merits. Even if they were sufficiently reliable to cover most cases, they would eventuate in mediocrity. Dreyfus and Dreyfus outlined the difference between embodied skill and an algorithm, the skill being something that is so much part of an expert through experience that the skilled practitioner is barely aware of his or her own knowledge.¹⁰³ They distinguish five levels of skilfulness, beginning with the novice and working up to the person with judgment informed by a lifetime’s experience. The detail of these levels is not important, but their conclusion is. In the first three levels of skill acquisition, algorithms are overall more helpful than not: in the highest two they actually impede excellence. You shouldn’t break the rules until the rules have become second nature – but then you *must* sometimes break the rules if you are to be successful and excel at what you do. Skilled pilots, surgeons, or commanders can often offer little insight, after having skilfully handled a crisis, into how they thought, or why they did what they did. Most often they say, ‘I just did what I had to’. Once questioned, they offer *post hoc* rationalisations, if anything at all.

As Kay puts it,

solving equations of motion is a means of understanding how well-judged shots find the goal, but it is not a means of making it happen ... People spend inordinate amounts of time asking experts like

Beckham what is the secret of their success. They don't come away much the wiser.¹⁰⁴

In politics, coming up with a list of clearly defined ends and then looking for the technical means of realising them most efficiently ignores the complexity, the many-strandedness, the non-absolute nature, of all ideals, of all knowledge, of all experience. The best of what we glean from experience is not technical in nature; and the kinds of knowledge it affords can be articulated only with great difficulty and subtlety, and are the first kinds to be ignored in articulation. They are acquired, honoured and transmitted only through our participation in a community extending over time in which we are immersed, and from which we take our very identity as individuals, our distinctness, even our capacity for intelligent opposition to received wisdom – what is called a tradition.

Beyond all such considerations, many rational and desirable goals are simply incompatible with the state of mind required to pursue them: they must come, if they come at all, as the by-products of a life well lived. Among these are humility, courage, love, admiration, faith and understanding. As the philosopher Jon Elster points out, in his brilliant book *Sour Grapes* (subtitled *Studies in the Subversion of Rationality*), trying to bring about such states directly is a moral fallacy. The corresponding intellectual fallacy is the attribution of such states, when they occur, to intentional action.

It's not just that linear thinking may be unproductive, even self-defeating, when applied to the setting and pursuit of goals. It's that, more generally, linear thinking may not get us past first base: instant apprehension of a *Gestalt* is our only chance to understand certain things. 'Some things are such that if you do not understand them immediately, you never will', wrote Mme de Sévigné.¹⁰⁵ This insight, too, is something you must already have – if not, I cannot help you. An understanding can never be given to another; it has to be awoken within them, and so must be there, in latent form already. Reasoning about it, evaluating it, and then deciding to acquire it will lead you nowhere. This thought lies behind many insights of the Oriental wisdom tradition. Thus, in the *Chuang Tzu* it is written: 'if you have not already got it in you, you cannot receive it'.¹⁰⁶ And in Zen Buddhism,

the belief that there is a doctrine to be known appears to be a sign that one has not yet understood anything (the misunderstanding, however, may be indispensable for ultimate understanding).¹⁰⁷

Zen masters do, after all, take on pupils. The point that one has to operate in a paradoxical way – pretending there is something to know, in order that others may discover in themselves that there is nothing to *know*, and thus gain true knowledge – is an example of how one has to think on many levels, not just one. There are different kinds of knowledge involved here, as there are different kinds of innocence. There is an innocence of the inexperienced, that of the child, and there is an innocence that lies on the other side of experience – one that is rarely achieved, that of the sage. Similarly, the knowing that there is nothing to know cannot be simply achieved at this moment, by a cognitive act, while you read the sentence. You must labour to know, meanwhile hoping that unknowing may come to you. It is as far from ignorance as can be.

I spoke of Carse's finite games that are played for the sake of winning, and his infinite games that are played for the sake of the game. Yet here, too, there are levels. The infinite game must involve, at one level, and to a certain degree, a desire to win, otherwise the game will not be satisfying *even if played for its own sake*. A game of tennis in which neither party (or only one) has the slightest intent to compete, at some level, will not be a game that satisfies at the higher level, at which competition is, quite genuinely, not the point.

I mention this to draw attention to the idea that what often looks paradoxical does so because the different levels of understanding have been flattened out. Just because at one level we don't want to win doesn't rule out that, on another level, we do – at least to some extent. Thinking of them as on the same level, makes us want to do a sum: 'how much you want to win' plus 'how much you don't', so that the oppositional element will be cancelled out (as +3 and -4 can be summed to a single quantity, with a single sign: -1, as though one just didn't care much at all). But it doesn't take into account that sometimes one wants or admires two entirely contradictory things passionately without being certifiably mad. Both must be retained *at the same time* – on different levels. Not just in different compartments on the same level, but on different levels: the point is important.

Although paradox can fruitfully be thought of as the two ends of a dipole, another way of expressing the coming together of opposites is not in terms of a straight line, but of a curve, prolonging each end until one comes 'full circle'. However, it may be not so much a case of coming full circle as 'full spiral', so to speak. *Not* that when you go far enough in one direction you arrive precisely where you started from, but that you arrive at a position superimposed on that from which you started, at the next turn of the spiral. This is why Eliot says, truly, that over a lifetime one keeps arriving at a fresh understanding of what seems to be the same imponderables, the same words, the same set of circumstances, images or ideas: 'And the end of all our exploring / Will be to arrive where we started / And know the place for the first time.'¹⁰⁸ According to the literal interpretation of the left hemisphere, to arrive back where you started is to have gone nowhere. But in seeing something we thought we knew afresh, it becomes both familiar and strange: we not only recognise it, but re-cognise it.

'Where would the difference be between great art and pure fancy?', wrote Bergson. 'If we reflect deeply upon what we feel as we look at a Turner or a Corot, we shall find that, if we accept them and admire them, it is because we had already perceived something of what they show us. But we had perceived without seeing.'¹⁰⁹ It seems to me that good philosophy is of this kind: that the mind is awakened to something it feels it always knew but never saw. This is what Plato called an un-forgetting: *anamnesis*.

We appear to ascend a spiral, like a staircase from which we can look down on our former vantage point. Very few writers have written more interestingly, and none more eloquently, of the coming together of opposites than William Blake. Even the titles of some of his most famous books of poems – the *Songs of Innocence and Experience*, *The Marriage of Heaven and Hell* – speak of this insight into the dipolar nature of reality. Jacob's Ladder, the staircase that leads from earth to heaven, is an image of spiritual progress. All the depictions of Jacob's Ladder I have ever seen show a straight staircase leading into the heavens – except Blake's, which moves very beautifully in a spiral. As we ascend we see how we thought we had the truth when we didn't, lower on the staircase, and how the staircase winds upwards as far as we can see (see Plate 14).

Many situations that we have been trained to think of two-dimensionally as a linear sequence are more like a sphere, or a three-dimensional net: not linear and flat, but round and having depth. The four

fundamental forces in physics all work like this, as 3-D fields, or flows, not as 2-D lines or chains. Human societies are like spheres, too – as in any complex system, there are many re-entrant loops. The idea of a sequence of causative steps breaks down, since nothing alters another thing without itself being altered; and, as I suggest, there are no wholly separate ‘things’ in any case.

But I have not yet tackled the real problem with linearity, which is the difference between a causal chain and a flow. This is what the historian of mathematics Morris Kline called the ‘difficulty that preoccupied all the Greeks, namely, the relation of the discrete to the continuous’.¹¹⁰ It is relevant here, as everywhere, but I need to postpone examination of this crucial distinction to the next chapter. There is ground to prepare.

We often imagine that science, philosophy and understanding of all kinds progresses by adding new bricks to the path that the seeker after understanding must tread. But it is not so. Instead, a new picture comes into focus, as things ‘fall into place’: a new *Gestalt* is revealed, which ‘answers’ better to the whole of one’s experience, accommodating a richer array of meanings, than the one it replaced. The spiral accommodates simultaneously a direction and a circular motion, at each point along its trajectory offering a new vision in the round, not just the blinkered vision of the forward running line, locked to its already conceived target. In the end, it is a matter not just of cognition, but of re-cognition. The ‘re-’ here functions not to indicate just sameness but also change, as it does in re-design, re-align: it is, as Jan Zwicky points out, a *Gestalt* shift.¹¹¹

The remarks of the great German mathematician and physicist Hermann Weyl are interesting in this regard. Weyl contrasted algebraic (linear) thinking with topological (figural) thinking, suggesting that we need to be able to draw on both, but that, of the two, algebraic thinking is relatively blind. He wrote:

We are not very pleased when we are forced to accept a mathematical truth by virtue of a complicated chain of formal conclusions and computations [left hemisphere fashion], which we traverse blindly, link by link, feeling our way by touch. We want first an overview of the aim and of the road; we want to understand the *idea* of the proof, the deeper context [right hemisphere fashion] ...¹¹²

We need both – that is the point. It's just that, as Weyl makes clear, though they are both valuable, one sees more deeply than the other.

According to his obituary by Freeman Dyson, Weyl 'alone could stand comparison with the last great universal mathematicians of the nineteenth century, Hilbert and Poincaré. So long as he was alive, he embodied a living contact between the main lines of advance in pure mathematics and in theoretical physics. Now he is dead the contact is broken'.¹¹³ Weyl had the simultaneous breadth and depth of vision that enabled him to tie together an insight into *different types* of mathematical and scientific thought with truth and beauty. 'My work', Weyl said, 'always tried to unite the true with the beautiful; but when I had to choose one or the other, I usually chose the beautiful.'¹¹⁴ Although initially some of his work in physics was rejected, on the basis that it seemed to conflict with the experimental results then available, the subsequent formulation of quantum mechanics led to an acceptance of the important truth of Weyl's work. Thus, as in the case of Schrödinger, before the full scientific facts were known, the sheer beauty of Weyl's work anticipated its truth.

But it is the differentiation between what are clearly left hemisphere and right hemisphere strategies, and their relation with beauty, that is so striking: 'A modern mathematical proof is not very different from a modern machine, or a modern test setup: the simple fundamental principles are hidden and almost invisible under a mass of technical details.'¹¹⁵ His observation clearly applies to a change in the scientific literature with which I am most familiar, that of neuropsychology, over the last 30 years or so. Papers which were lucid and beautiful, and full of humanity (particularly if one goes back as far as the early to mid-twentieth century French and German literature) have yielded to something like a machine process, with the philosophical and human element 'almost invisible under a mass of technical details'. Be that as it may, Weyl is here contrasting the unattractive, mechanical amassing of details, the 'blind' following of serial processes, with the more pleasing insight into the whole, the context and the overall path to be traversed. Similarly,

the system of real numbers is like a Janus head with two oppositely directed faces. In one respect it is the domain of the operations + and \times and their inverses [left hemisphere]; in another it is a continuous manifold [right hemisphere], and the two are

continuously related [right hemisphere's synthetic take on both]. One is the algebraic and the other is the topological face of numbers ... neither one of the two ways of understanding, the topological or the algebraic, can be acknowledged to have unconditional advantage over the other ... In topology we begin with the notion of continuous connection ... Algebra views [its] operations as the beginning of all mathematical thinking, and *admits continuity*, or some algebraic *surrogate* of continuity, *at the last step* of specialization. The two methods follow opposite directions. Little wonder that they don't get on well together. What is most easily accessible to one is often most deeply hidden to the other. Such classical theories as that of algebraic functions can be made to fit both viewpoints. But viewed from these two viewpoints they present completely different sights. ¹¹⁶

Note that in conveying these two ways of understanding mathematics, Weyl contrasts one that is 'continuous' or 'topological', suggestive of the right hemisphere, with one that is made up of serial 'operations' (procedures) carried out on 'algebraic' signs (abstract discrete entities), suggestive of the left hemisphere. Both are, however, related 'continuously', that is by the process of the right hemisphere, though neither has unconditional advantage. Algebra 'views' its operations as grounding the process, but has to admit the continuous at some point, which it postpones until 'the last step'. They see different things and 'don't get on well together'. However:

whenever applicable, the topological method appears, thus far, to be more effective than the algebraic one. Abstract algebra has not yet produced successes comparable to the successes of the topological method ... I do not want to conceal from you the growing feeling among mathematicians that the fruitfulness of the abstracting method is close to exhaustion. It is a fact that beautiful general concepts do not drop out of the sky. The truth is that, to begin with, there are definite concrete problems, with all their undivided complexity, and these must be conquered by individuals relying on brute force. Only then come the axiomatizers and conclude that instead of straining to break in the door and bloodying one's hands

one should have first constructed a magic key of such and such shape and then the door would have opened quietly, as if by itself. But they can construct the key only because the successful breakthrough enables them to study the lock *front and back*, from the outside and from the inside.¹¹⁷

Once the intuition gets you in the door, you can figure out how to unlock it. Once a leap of intuition gets you to your conclusion, you can reconstruct a path that you might have taken – but did not in fact take – to get there. This has something to say to the nature of reason, namely that it needs to transcend its intrinsic limitations in order to be able to operate rationally.

Jacques Hadamard similarly commented that ‘any mathematical argument, however complicated, must appear to me as a unique thing. I do not feel that I have understood it as long as I do not succeed in grasping it in one global idea’.¹¹⁸ And he also emphasised the suddenness of insight, which he repeatedly likened to a strike of lightning.¹¹⁹ Yet at the same time, he draws attention to the fact that insight does not, as Weyl puts it, ‘drop out of the sky’: there is a period of preparation, during which an exertion is made, a period which is often long and exhausting. It is in the state of fatigue after this exertion, when the mind relaxes, that the illumination comes. In fact he comments that it is ‘as though it were necessary for the conscious self to be weakened in order that unconscious ideas may break through.’¹²⁰ In our own day this view of mathematical thought as requiring the transcendence of computational methods that could be made explicit is in keeping with the view of Roger Penrose, as set forth in his *Shadows of the Mind*: mathematical invention cannot be modelled as computation.¹²¹

Unsurprisingly, there is a parallel distinction to be made among philosophers as there is among mathematicians. As Jan Zwicky suggests:

Philosophers fall into roughly two classes: those who trust their perceptions more than they trust language, and those who trust language more than they trust their perceptions. Berkeley and Herakleitos fall into the first class, Locke and Parmenides into the second. And, although we don’t take sufficient notice of this, to each class there *also* corresponds a distinct notion of abstract thought:

members of the first class tend to think of it as a grasp of structural features [seeing the patterns] ... while members of the second tend to think of it as the logico-linguistic manipulation of non-structurally-conceived placeholders [algebra].¹²²

There is, as discussed previously, a peculiar bias towards language and naming in Western culture.¹²³

In the 1960s, the architect and philosopher Christopher Alexander asked women students at a top American college, Radcliffe, to arrange short strips of paper consisting of random segments of black and white, in any way they chose. What interested him was that there were effectively two strategies for doing so. One might be described as sequential-digital, the other as figural-holistic. He saw that the first was ‘less interesting, and ... functionally less likely to be important in the behavior of real systems’. The second was ‘deeper and more interesting’, since it was more pertinent to the study of real physical systems such as emerging galaxies or developing embryos. He wanted to see what these young women, highly intelligent, but highly educated, made of it all. He found that 80% chose the sequential-digital approach, only 20% the figurative-holistic.¹²⁴ This is a tendency that is more marked in Westerners than non-Westerners, and in part reflects the *Einstellung* effect discussed in Chapter 4. (He assumed that the results would be the same for women as for men; as I showed in the same chapter, men tend to think more holistically, women more sequentially, so this result has to be interpreted in that light.)

We have seen that scientists and mathematicians, just like artists, make discoveries by having moments of insight into analogous forms, guided by intuition, hardly ever, if at all, by following a sequential process. On this the historical record is very clear. Insights may come on the back of much routine slog, but the moment of insight itself never comes this way. To take just two famous examples: Einstein thought in musical shapes; Bohr’s notebooks contain no words or formulae, just pictures. So why is it that our education is largely geared to learning how to carry out rote procedures in a sequential, linear fashion?

We can kill creativity by instituting regular ‘procedures’ and closely monitoring the process – all of which the left hemisphere does best. This succeeds in over-controlling the ‘product’, and ensuring mediocrity (though without, of course, avoiding mistakes). It rules out anything not explicit,

and already foreseen in the schema. And it discourages analogical thinking: seeing the patterns that come to us through intuition. It's not new procedures we need: it's new shapes, new *Gestalten* – new wholes.

THE IMPERSONAL VS THE PERSONAL

We are inclined to be too easily persuaded by the rhetoric of academic philosophy into thinking that there is something impersonal, pure and eternal about the sort of reasoning in which it engages. Much as the beaker *was placed* in the fume cupboard, apparently without the intervention of anything so fallible as a human hand, we imagine that such reasoning carries no taint of flesh about it. We overlook the nature of the philosopher, and thus of the very particular nature of philosophical discourse, to which it is indissolubly linked. It is easy to forget that philosophical discourse is only one way of understanding the world, and inevitably a personal one. Personal elements come in different forms, but are inescapable, since what Thomas Nagel calls the ‘view from nowhere’ is impossible, and the very attempt does little more than speak of the personality making it. We cannot abstract philosophy from the happenstance of the physical being that dreamed it up.

To engage in philosophy is, I believe, as much a response to an instinct as to engage in science. Philosophers might be unlikely to agree. Or would they?

The idealist philosopher FH Bradley wrote that ‘metaphysics is the finding of bad reasons for what we believe upon instinct, but to find these reasons is no less an instinct.’¹²⁵ That reasons often come late in the process, and are retro-fitted, is a point emphasised by the philosopher Francis Cornford:

Almost all philosophical arguments are invented ... to recommend, or defend from attack, conclusions which the philosopher was from the outset bent upon believing ... To mistake [philosophical reasonings] for the causes which lead to a belief in the conclusion, is generally to fall into a naïve error.¹²⁶

Economist John Kay has some incisive thoughts on this matter, in relation to what Benjamin Franklin called ‘moral or prudential algebra’, a process in which one sets out pros and cons, attaches numerical weights to

each consideration, and arrives at a balanced, and therefore, impartial moral judgment. Here is Kay's account:

Franklin knew very well that this is not how real people, including himself, behaved. Franklin was an occasional vegetarian, having balanced the moral, nutritional and practical arguments. But confronted with the delicious smell of freshly grilled fish, he observed that the fish themselves disregarded his precepts by eating other fish and so deserved to be eaten. 'How convenient it is', he said, 'to be a reasonable creature, since it enables one to make or find a reason for whatever one has a mind to do.'¹²⁷

Franklin, who had a well-developed sense of humour, was surely speaking tongue in cheek, but the point is nicely made – and very real.

Temperament counts for much in what we find in the world. Fichte wrote that the

sort of philosophy one chooses depends ... on what sort of man one is; for a philosophical system is not a dead piece of furniture that we accept or reject as we wish; it is rather a thing animated by the soul of the person who holds it.¹²⁸

There is a difference between the view of philosophy as an edifice and as a dwelling. (Incidentally, the original meaning of the Greek word *ethos*, from which the word 'ethics' derives, is 'dwelling place').¹²⁹ In the one view it is something *constructed*, piecemeal, as it were from the outside; in the other it is something coming about through being lived, as it were from the inside. 'Place yourself', writes William James,

at the centre of a man's philosophic vision and you understand at once all the different things it makes him write or say. But keep outside, use your post-mortem method, try to build the philosophy up out of the single phrases, taking first one and then another and seeking to make them fit, and of course you fail. You crawl over the thing like a myopic ant over a building, tumbling into every

microscopic crack or fissure, finding nothing but inconsistencies, and never suspecting that a centre exists.’¹³⁰

Note ‘post-mortem’. Philosophy is not, then, purely a matter of impersonal reason, but living: bound up in the temperament, character and history of the person who expounds it. As Dewey pointed out, ‘every particular case of thinking is what it is because of some attitude, some bias’ and, as for the philosopher, ‘when he becomes a thinker he does not leave his characteristic affection [inclination] behind.’¹³¹ Moreover Wittgenstein, too, thought that ultimately differences of temperament lay behind many philosophical disputes;¹³² and William James wrote frankly that ‘the history of philosophy is to a great extent that of a certain clash of human temperaments.’¹³³

So, when we set out to investigate the world objectively, are we at the end of the day only reporting on ourselves? ‘However far man may extend himself with his knowledge, however objective he may appear to himself’, wrote Nietzsche, ‘ultimately he reaps nothing but his own biography.’¹³⁴ Elsewhere he expanded the idea:

It has gradually become clear to me what every great philosophy has hitherto been: a confession on the part of its author and a kind of involuntary and unconscious memoir ... I accordingly do not believe a ‘drive to knowledge’ to be the father of philosophy, but that another drive has, here as elsewhere, only employed knowledge (and false knowledge!) as a tool. ¹³⁵

This is intriguing, because of my belief that the *raison d’être* of the left hemisphere, which is to manipulate the world, underlies the coercive drive implicit in logical argument: as Nietzsche puts it, another ‘drive’, a will to power, acts under cover of an apparently impeccable, because *impersonal*, aim in order to achieve its own ends. It is not just that philosophy can never free itself from personality: a person’s philosophy may be doing *psychological work for that personality*, which might explain why philosophies are so passionately defended. Nietzsche continues:

even apart from the value of such claims as ‘there is a categorical imperative in us’, one can still always ask: what does such a claim tell us about the man who makes it?

Rather more trenchantly, Iris Murdoch wrote: ‘It is always a significant question to ask about any philosopher: what is he afraid of?’¹³⁶ In many cases it would seem to be uncertainty, vulnerability, laying oneself open to truth from experience – and to hell with the theory.

Though I confess to a lifelong addiction to it, there is a sense in which philosophy is in itself an unhealthy activity: the disease, perhaps, as Karl Kraus said of psychoanalysis, for which it purports to be the cure. Jung wrote:

For all its critical analysis philosophy has not yet managed to root out its psychopaths ... Philosophy still has to learn that it is made by human beings and depends to an alarming degree on their psychic constitution. In the critical philosophy of the future there will be a chapter on ‘The Psychopathology of Philosophy’ ... Often what is thought is less important than who thinks it. But this is assiduously overlooked. Neurosis addles the brain of every philosopher because he is at odds with himself. His philosophy is then nothing but a systematised struggle with his own uncertainty.¹³⁷

Indeed – well, sometimes. And the point here is, not just that philosophy is reflective of any old psychopathology that just happens on an individual basis to be present, but that a certain kind of unusual mind is preferentially and systematically attracted to philosophy of the analytic kind. This is a mind somewhere down the schizo-autistic spectrum, as many examples of now famous philosophers in the analytic tradition attest. For a philosopher such as Collingwood, imagination and empathy, the appreciation of context, both personal and historical, as well as the ability to feel your way into another’s mind (all skills that are highly right hemisphere-dependent), play a crucial role in understanding, ‘unlike philosophers in the Ryle mould’.¹³⁸

‘Philosophers in the Ryle mould’ are more likely to take things out of context, think in disembodied schemata, and adopt irrationally rationalistic approaches. They tend towards utilitarianism in ethics, an approach that is

also characteristic of people with frontal lobe damage, especially in the right hemisphere, the clinical picture of which resembles some types of autism.¹³⁹ Which is not, of course, to say that all utilitarian philosophers are autistic – or that psychopathology makes the perceptions of its sufferers invalid: it may actually make some things easier to see, while hiding or distorting others. But it does invite the question why we should attach particular importance to a way of looking at the world which is typical of a spectrum of conditions which normally lead to their holders receiving treatment for a distressing illness.

According to Louis Sass's observations of schizophrenia, madness may be 'the endpoint of the trajectory consciousness follows when it separates from the body and the passions, and from the social and practical world, and turns in upon itself' – the more the world is purely cognitive, the closer madness and philosophy come together.¹⁴⁰ And as Sass has demonstrated, one can see from both Wittgenstein's notebooks and from Schreber's self-account that in both a position of alienation makes for a sense of unreality.¹⁴¹ Hannah Arendt suggested that philosophy, as she knew it, was something unnatural and 'out-of-order', something *contrary* to the health of the human condition.¹⁴²

Detachment is certainly necessary in some contexts, but it does not always and alone lead to better insights than engagement. Indeed, it may be safer to recognise the degree to which our minds, bodies, emotions and the environment are indissolubly linked than to pretend that they are not. And not just because these elements are some form of 'bias': the failure to take them into account may also lead to bias – distorted perceptions and a limited understanding of what one is dealing with. The closest humans get to being cut off from feelings, the body and the self is achieved not by great scientists, but by subjects with schizophrenia.¹⁴³

Nietzsche amusingly comments, alluding to his idea of philosophy as an involuntary autobiography, that, in the case of Kant, it was not even 'an involuntary biography of a soul but ... the biography of a *head*.'¹⁴⁴ Roger Scruton points out that the great modern philosophers have tended to 'avoid the experience of desire as scrupulously as they have tended to avoid its analysis'.¹⁴⁵ He quotes Kant's description of marriage as an agreement between two people as to the 'reciprocal use of each other's sexual organs'. He might also have quoted Spinoza on love: 'titillation accompanied by the

idea of an external cause'.¹⁴⁶ But Freud's attitude to sexual desire is almost as expressive of a sort of fastidious alienation, its aim, according to him, being the 'union of the genitals in the act known as copulation, which leads to a release of the sexual tension and a temporary extinction of the sexual instinct – a satisfaction analogous to the sating of hunger.'¹⁴⁷ He described the task of psychoanalysis as drying up the messy emotions of the patient. 'Where Id was, there shall Ego be', he declared somewhat portentously. 'It is reclamation work, like the draining of the Zuyder Zee'.¹⁴⁸ Perhaps Freud's biographer Ernest Jones could be referring to his own mentor, among others, when he suggested that philosophers are people who have been 'impelled to deal with various personal problems in their unconscious by making serious efforts to think consciously; they have intellectualized the emotional conflicts.'¹⁴⁹ The recommendation in Freud's technical papers for analysts to be emotionless, according to Ferenczi and Rank, had led to 'an unnatural elimination of all human factors' and to 'a theorizing of experience'.¹⁵⁰

Approaching the relationship between philosophy and autism from the other direction, it is not just that there may be something autistic about certain philosophical styles, but there is a certain philosophical style to the pronouncements of subjects with autism. Tony Attwood, an acknowledged expert on the autistic spectrum, writes that there is a 'quasi-philosophical quality' to the autobiographies of adults with Asperger's syndrome.¹⁵¹ What he is referring to is generally accepted to be an over-rationalistic, hyper-reflexive self-awareness, and a disengagement from emotion and embodied existence, which is very much in accord with my experience of looking after subjects on the autistic spectrum. Moreover, there is an abstract, quasi-philosophical mode of talking that is common in some kinds of schizophrenia, at first impressive, but ultimately recalcitrant to understanding; it is sometimes actually referred to as 'pseudo-philosophical thought disorder'.¹⁵² Both autistic and schizophrenic individuals have an antipathy to what is embodied, uncertain and unknown (or unknowable), preferring what is abstract, certain and known, all of which is characteristic of the left hemisphere.

There is something like a sickness of the soul in requiring proof (in the left hemisphere sense) of absolute certainty. Thus Merleau-Ponty wrote:

If I like, I can always be strict and put in doubt the reality of the other's feelings towards me; this is because such feelings are never *absolutely* proved ... the normal, non-pathological attitude consists in having confidence above and beyond what can be proved ... by means of the generosity of the *praxis*, by means of an action that proves itself in being carried out.¹⁵³

The word 'generosity' there is not idle. There can be at times a hint of something mean and suspicious about calculation and the need for proof – a failure of trust. Life is an intrinsically exuberant, superabundant business, and to respond to it in a calculating spirit is an offence against nature. 'O reason not the need', cried Lear, when his daughters tried to calculate what he could get by without: could Lear's outrage still be understood in this era of accountancy?

Here I might make an aside on the philosophical personality. If I am right, as I argued in Chapter 9, that schizo-autistic features suggest a tendency to left hemisphere modes of apprehension of the world, and depressive features suggest the opposite, one would expect highly analytic philosophers to have character features suggesting they are on the schizo-autistic spectrum. Descartes had many hallmarks of the schizoid personality;¹⁵⁴ Spinoza and Kant were probably on the autistic spectrum, and so, clearly, was Bentham; in modern times there is a case that Bertrand Russell, AJ Ayer, and Derek Parfit also were, to name a few.¹⁵⁵ Similarly, one might expect philosophers who were opposed to the analytic tradition to be more prone to depression; it is arguable that Pascal, Hegel, Kierkegaard, Emerson, CS Peirce, William James and John Dewey were.¹⁵⁶ Wittgenstein is an intriguing case here, because the early Wittgenstein of the *Tractatus* was highly analytical, though his very purpose was to show the limits of linear analytical reasoning: he thought that logic and propositionalising left all matters of value untouched. Appropriately, then, it is well known that he had many features of a schizoid personality¹⁵⁷ and of Asperger's syndrome;¹⁵⁸ but, particularly latterly, he also suffered from bouts of depression.¹⁵⁹

Let me be quite clear: people are massively complicated, and except perhaps in extreme cases, you can't put people in boxes marked 'left' and 'right'. Since the right hemisphere is always aware of the need for the left,

and the left not aware of the need for the right, it is always going to be more clear-cut, more obviously unbalanced, when the tendency is to adopt left hemisphere modes of thinking. That is why I have structured my comments on philosophers as a *relatively* clear relation between the left hemisphere and those of the analytic tradition – versus the rest. The ‘opponents’ I have mentioned were also perfectly capable of analysis. They would have subscribed to Pascal’s ‘two excesses: to admit only reason or to rule it out’. It’s just that analytic types usually see only one of these two excesses.

Since, clearly, retrospective diagnoses are prone to error, autistic spectrum conditions not infrequently overlap with depression, and there must undoubtedly be counter-examples, why bring it up at all? Because there might just be *something* in it. For example, in an unpublished study, which I carried out as a Medical Registrar in the 1980s, of the degree subjects undertaken by approximately 200 university students who then went on to be admitted to the Bethlem Royal & Maudsley Hospital in London during a psychotic episode, I found that a subsequent diagnosis of schizophrenia was most strongly associated with having chosen to study engineering, followed closely by philosophy ($p > 0.001$). The abstract, impersonal, sequentialist approach of philosophy distinguishes it from all other humanities subjects (eg, literature, history), which require more understanding of humanity in the round, and which were the commonest degree choices amongst those who were subsequently diagnosed with an affective psychosis (psychotic depression or bipolar disorder).

My purpose here is neither to romanticise psychopathology nor to give a reductive account of philosophy, but to illustrate the inevitable connexions between individual psychology and philosophy, so often commented on by philosophers themselves. We cannot divorce the philosophy from the philosopher. I am sure that saying this will be resisted by many, and resented by some – but, though you can ignore it, it is hard to deny its truth. The options are to remain in denial (left hemisphere-preferred strategy) or to use the knowledge to avoid pitfalls (right hemisphere-preferred strategy).

Most appositely of all, the philosopher Paul Feyerabend wrote:

Schizophrenics very often hold beliefs which are as rigid, all-pervasive, and unconnected with reality, as are the best dogmatic philosophies. However, such beliefs come to them naturally, whereas a ‘critical’ philosopher may sometimes spend his whole life

in attempting to find arguments which create a similar state of mind.¹⁶⁰

It is a fascinating reflection. Two of the greatest phenomenologists of schizophrenia, Eugène Minkowski and Wolfgang Blankenburg, suggested that schizophrenics attempt to compensate for a loss of intuition, of that vital, pre-reflective grasp of reality, by a sort of pseudo-philosophising, or ‘hyper-reflection’ on experience – essentially a disease of over-awareness, in which things that should run smoothly at the preconscious level are yanked into the focus of awareness, where life comes to a juddering halt.¹⁶¹

Schizophrenics are in fact *more*, not less, logical than normal subjects, and deficient in common sense.¹⁶² The theme has been explored by a number of contemporary psychologists and psychiatrists, such as Louis Sass and Giovanni Stanghellini.¹⁶³ It could explain a lot about contemporary academic philosophy, such as brains in vats, and various types of Cartesian scepticism, not to mention the denial of consistent human persons, or – most bizarre of all – the denial by intelligent human beings of conscious experience itself.

Since philosophy is related to individual psychology, the influence might run either way. Am I right to assume that, in my study of 200 psychotic subjects who broke down while studying at university, psychopathology influenced the choice of philosophy as a subject of study, rather than that philosophy as a subject of study actually precipitated episodes of psychosis? Probably, as usual, the answer is that both might operate to some degree: the process is not linear but circular. I had a patient, a philosopher, who suffered from obsessive-compulsive disorder: he reported that he was quite well as long as he was studying phenomenological philosophers, with their acceptance of uncertainty, but not when he was studying analytical philosophers, with their intolerance of it. Then it was that he developed OCD (obsessive-compulsive disorder) symptoms.

There may be something damaging to the whole character of a person in spending a life in abstract reasoning, whether in philosophy or science. I think of a famous, and touching, passage in Darwin’s *Autobiography*:

I have said that in one respect my mind has changed during the last twenty or thirty years. Up to the age of thirty, or beyond it, poetry of many kinds, such as the works of Milton, Gray, Byron, Wordsworth, Coleridge, and Shelley, gave me great pleasure, and even as a schoolboy I took intense delight in Shakespeare, especially in the historical plays. I have also said that formerly pictures gave me considerable, and music very great delight. But now for many years I cannot endure to read a line of poetry: I have tried lately to read Shakespeare, and found it so intolerably dull that it nauseated me. I have also almost lost my taste for pictures or music ... My mind seems to have become a kind of machine for grinding general laws out of large collections of facts ... and if I had to live my life again, I would have made a rule to read some poetry and listen to some music at least once every week; for perhaps the parts of my brain now atrophied would thus have been kept active through use. The loss of these tastes is a loss of happiness, and may possibly be injurious to the intellect, and more probably to the moral character, by enfeebling the emotional part of our nature.¹⁶⁴

As they say, be careful what you wish for. Some 20 years earlier, in a letter to Huxley, Darwin had written: ‘alas’ – and how I respect that ‘alas’ – ‘a scientific man ought to have no wishes, no affections, – a mere heart of stone.’¹⁶⁵

Before we move on, let me not duck the question of how much my own thinking is shaped by the sort of person I am.

Inevitably my personality is, as I have argued, bound to underwrite my thinking. Although I count myself very fortunate and get a lot of fun out of life, I have had several episodes of depression over my lifetime, mercifully well contained, but devastating while they lasted. And I have always had a passion for nature and for art. I suspect my overall temperament makes me sympathetic to the right hemisphere’s outlook, in as much as these things have any validity.

I think it is also true that my personality has guided my preoccupations. As a young man I was lamentably perfectionistic: it may lie behind my desire to decry the barrenness of perfection. (The book I wrote in my 20s called *Against Criticism* was at one stage going to be called *The Importance of Imperfection*. When the proofs came, I rang my editor with a fifth round

of corrections, which included a comma in the wrong font. She accepted the correction, but suggested that it might be a good idea if I now took a holiday.) But, at least, it made me want to argue *against* the value of perfection, not to propagate it. Many of the things I argue for I have – like many philosophers, as we have seen – felt obscurely all my life to be important. Whether that counts against them or for them I cannot say. On that point, it might be worth recounting a story of Niels Bohr:

Bohr never referred to his philosophy as his own. He used to speak of it as a general lesson to be drawn from quantum mechanics. Yet when, shortly after the development of quantum mechanics, he told his old friend Edgar Rubin, the psychologist, of this general lesson, Rubin replied, ‘Yes, it’s very interesting, but you must admit that you said just the same thing twenty years ago’ ... Bohr has said that as far back as he could remember he liked to dream of great interrelationships. His philosophical attitude seems to have been shaped early with very little influence from outside, and he spent much time developing it. Shortly before his death Bohr spoke of his youthful philosophical work. When asked what place this work then had in his existence, he replied, ‘It was, in a way, my life!’¹⁶⁶

Someone once asked me, acutely, after I quoted the line of Iris Murdoch, ‘so what are *you* afraid of?’ I don’t remember my answer. At this stage, with death not far off, I don’t fear anything much that I am aware of, not even death, as long as it doesn’t come too soon for me to finish this book. In the past I was afraid of stepping out of line too much and making a fool of myself. Now that I know how foolish we all are, I am happy to be just another human being.

With respect to the major themes of this chapter, in writing this book I have found it necessary to move back and forth between the distance that makes possible the detection of patterns, on the one hand, and the immediacy of experimental data and experience with patients, on the other, out of which the patterns emerge. To the extent that I have succeeded, it represents an example of fruitful hemispheric co-operation: aiming not to construct a linear structure of hard-edged categories, but to bring into focus a new *Gestalt*. In doing this I have aimed to combine precision about findings, with tolerance of necessarily imprecise structures in the process of

bringing the whole into focus, so as to be faithful to the findings; since precision at too early a stage of resolving the *Gestalt*, throws the whole structure out. In changing a wheel on a car, one does not fully tighten any one bolt until all are roughly in alignment. Science is not like building a wall, where the first steps must be fixed in advance of the rest: it is about bringing our ideas and the world into alignment, a reverberative, not a linear process. Whitehead puts it well:

The true method of discovery is like the flight of an aeroplane. It starts from the ground of particular observation; it makes a flight in the thin air of imaginative generalization; and it again lands for renewed observation rendered acute by rational interpretation. ¹⁶⁷

And so for many iterations. In doing this I have wrestled hard to press abstraction, precision and linearity and all the other rational progeny of the left hemisphere in the service of their opposites. That is suitably paradoxical at one level; quite logical at another.

LOGOS VS MYTHOS

Where do all these twins leave us when considering the nature of Reason's assistance in our attempts to approach truth? I would suggest that our culture has tended to fall for the persuasive power of those twins that claim paternity by the left hemisphere, leading us to expect truth, or at least our attempts to express it, to be clear, precise, impersonal, probably abstract and unreasonably certain. In sum, we expect our truths to be something which we casually designate 'literally true'; anything that isn't 'literally true', we tell ourselves, isn't true at all. The opposite members of each pair of twins not only warn that these are false claims, but point, however tentatively, to the truths which such a view has concealed from our sight. But most of all the cautionary twins warn us about literalism, reminding us that all expressions of truth are rooted in metaphor and that literal truth is a chimera.

The subject of literalism is close to my heart – as it was to my father's, though in a different sense. My father was a decent, devoted, down-to-earth family doctor, who had no interest in novels, little in poetry, and none in classical music, especially none – perish the thought – in ballet or opera. It was the school holidays, and I was watching a televised relay of Mozart's *Don Giovanni* from Glyndebourne, when my father came into the room. The opera had barely begun, and it was that dramatic moment when the Don has just fatally wounded the dignified Commendatore, the veteran soldier and father of the Don's catch of the moment, Donna Anna, by a blow to the heart in a duel over his daughter's honour. The Commendatore lies dying, the violins are delivering throbbing arpeggios, and the old man, lying propped on one arm, sings in an urgent cadence: '*Ah, soccorso!*' – 'Help me!' There ensues the following conversation:

My father: 'What's this?'

Me: (tentatively) 'It's – Mozart ... an opera called *Don Giovanni*.'

My father: 'Well, that's ridiculous.'

Me: 'What's ridiculous?'

My father: (dismissively) 'Well he's just sustained a pneumothorax.'

No-one can sing when they've sustained a *pneumothorax*.'

This judgment delivered, my father left the room to return to his latest book on archaeology, a sort of passion of his, since there were an abundance of facts, and mercifully few artefacts, to be dug up.

Although I suspect my readers will want to distance themselves from this standpoint, I suspect also that some covertly share a modified version of it. For it has to do with the nature of truth. Science is what delivers truth, they will say – as indeed my father did. The arts deliver pretty, diverting, consoling – at times, they might concede, beautiful, engaging, and even disturbing – myths. Of which Mozart's *Don Giovanni* is one. But myths are, of course, false, aren't they? Nice enough to pass the time of day with, but nothing to do with truth.

Perhaps the best rant along these lines comes from William Cobbett, the late eighteenth- and early nineteenth-century farmer and political reformer, who wrote of *Paradise Lost*:

... the whole of Milton's poem, is such barbarous trash, so outrageously offensive to reason and to common sense, that one is naturally led to wonder, how it can have been tolerated by a people amongst whom astronomy, navigation, and chemistry are understood.¹⁶⁸

People who don't understand that myths are not to be taken literally, but nonetheless exist to express truths that everyday language is too limited, too narrow, too precise to convey, are like people who would dismiss Shakespeare's *King Lear* on the grounds that, according to the chronicles of Geoffrey of Monmouth, the historical Leir (as he was known prior to Shakespeare), fled to France, and with the help of Cordelia and her husband, overthrew his other daughters and sons-in-law, and was restored to the throne. Thus tactlessly ruining the tragedy. Or object that since Geoffrey's history, too, was of uncertain provenance, we know nothing reliable of the historical King Lear at all – if indeed he ever actually existed. Ergo, Shakespeare got it wrong.

The word 'myth', which derives from an ancient Greek word *mythos* (or *muthos*), was unknown in English, according to the *OED*, till just before the middle of the nineteenth century, when it was adopted by philologists and classical scholars to denote ancient stories – as opposed to ancient history. 'Story', by the way, is just an aphetic version of 'history', that is to say a

word form in which part has, over time, been lost. But as story and history separated, the status of a story became more ambiguous: there developed a slightly unfavourable assumption that it might not be true, whereas there is a presumption that history refers to something on which one can, more or less, rely. In modern English we even say ‘to tell stories’, meaning to *lie*. A similar fate has overtaken ‘fable’ (like ‘fate’ itself, from Latin *fari*, to speak: originally, ‘something that was spoken’, a narrative). Nowadays if narratives are considered fables, it is in the sense of untruths. And a legend was something proper ‘to be read’ (from the gerundive, *legendus*, of Latin *legere*, to read). According to the *OED*, it was only in the seventeenth century that ‘legend’ took on the meaning of something untrue.

There is a similar history to ‘metaphor’ (from Greek, *meta-*, across, + *pherein*, to carry), that which carries you over from an idea to an embodied experience. It is the root of all meaning: I cannot escape using the word ‘root’ here as a metaphor.¹⁶⁹ Yet by the seventeenth century, in the dawn of the new age of Enlightenment, Locke could write:

... all the artificial and figurative application of words eloquence hath invented, are for nothing else but to insinuate wrong ideas, move the passions, and thereby mislead the judgment; and so indeed are perfect cheats ...¹⁷⁰

And so it has been with ‘myth’. Alasdair MacIntyre points out the novelty, again arising at the Enlightenment, of the idea of ‘facts’ as reflecting a reality independent of our judgment:

Facts, like telescopes and wigs for gentlemen, were a seventeenth-century invention. In the sixteenth century and earlier ‘fact’ in English was usually a rendering of the Latin ‘factum’, a deed, an action, and sometimes in Scholastic Latin an event or an occasion ... It is of course and always was harmless, philosophically and otherwise, to use the word ‘fact’ of what a judgment states. What is and was not harmless, but highly misleading, was to conceive a realm of facts *independent of judgment or of any other form of linguistic expression*.¹⁷¹

It's not as if, until this use of 'fact' came along, no-one knew the difference between things that happened and things that hadn't. According to NT Wright, it is only with the new emphasis on certainty with the Enlightenment, 'with the suspiciously bright light of an incipient scientism', that facts suddenly come into prominence:

Everything else is suspect; give us facts. Science says, 'Well, we'll try'; scientism says, 'Here you are – and you must take our philosophy as well.'¹⁷²

A fact is presumed to be true independent of context. But no human knowledge is ever independent of context, even if only that it is human, and derived from experience. No world view can transcend such limitations – limitations that are by no means fatal to serviceable truths, but are fatal to the hubristic enterprise of accounting for the world fully in some impersonal way by what we call facts.

As Douglas Hofstadter points out, logic is neat and clean, but, if it is to lead to understanding, those very qualities get in the way:

Why should not logicians, more than anyone, realize the places where hard-edged, clean logic will necessarily run into trouble in dealing with this chaotic and messy universe? One of Marvin Minsky's favourite claims is 'Logic doesn't apply to the real world.' There is a sense in which this is true. This is one of the difficulties that artificial intelligence workers are facing. They are coming to realise that no intelligence can be based on reasoning alone; or rather that isolated reasoning is impossible, because reasoning depends on a prior setting-up of a system of concepts, percepts, classes, categories – call them what you will – in terms of which all situations are understood. It is there that biases and selection enter the picture. ¹⁷³

Or as Einstein put it succinctly: 'As far as the propositions of mathematics refer to reality, they are not certain; as far as they are certain, they do not refer to reality.'¹⁷⁴

One path to knowledge is logic, which we now think of as something literal and explicit. The Greeks, though, who, after all, invented what one might call the Western logical tradition, hardly invented logic. ‘Logic’, as Bruno Snell pointed out,

has been in existence ever since men have talked and thought; the reason why it did not, at first, find expression in speech was not that logic did not exist but that it was *implicit and understood*. As soon, however, as it is discovered, and intrudes into consciousness, human thinking undergoes a radical change ...¹⁷⁵

In other words, the Greeks did not invent logic; it’s just that what before had been the ground of our thinking was suddenly foregrounded. A spotlight was thrown on it, and this, as Snell says, changed everything. This difference between something remaining as the ground, and coming to be foregrounded, is an important theme of this book, since it refers to the different mode of operation of the two hemispheres. The left hemisphere’s attention latches onto the salient feature, what lies in the focus of attention, and effectively isolates it. The right hemisphere’s attention is to the whole scene, especially to the context or background in which the salient feature finds itself placed.

Whitehead sets this in the context of normal psychology:

It is a profoundly erroneous truism, repeated by all copy-books and by eminent people when they are making speeches, that we should cultivate the habit of thinking of what we are doing. The precise opposite is the case. Civilization advances by extending the number of important operations which we can perform without thinking about them. Operations of thought are like cavalry charges in a battle – they are strictly limited in number, they require fresh horses, and must only be made at decisive moments.¹⁷⁶

It could be said that the trouble with Western philosophy began with Plato’s foregrounding of *logos*. In the Greek world, as in most pre-modern cultures, there had always existed more than one way of acquiring an understanding of the world. The Greeks, let it not be forgotten, also gave

birth to many of the most enduring myths by which we understand our relationship to the world, such as those of Œdipus, of Prometheus, of the gods of the *Iliad* and of the *Odyssey*. There was, and is, no conflict here. Indeed they distinguished two types of truth, *mythos* and *logos*; each was considered essential in its own proper field, and the two were not to be confused. So Karen Armstrong writes:

Logos ('reason') was the pragmatic mode of thought that enabled people to function effectively in the world. It had, therefore, to correspond accurately to external reality. People have always needed *logos* to make an efficient weapon, organize their societies, or plan an expedition. *Logos* was forward-looking, continually on the lookout for new ways of controlling the environment ... *Logos* was essential to the survival of our species.

But *logos* had its limitations. Good at manipulating the world and making us powerful, it did not contribute to any broader understanding of the meaning of our lives – for that people turned to *mythos*. Armstrong continues:

Myths may have told stories about the gods, but they were really focused on the more elusive, puzzling, and tragic aspects of the human predicament that lay outside the remit of *logos* ... When a myth described heroes threading their way through labyrinths, descending into the underworld, or fighting monsters, these were not understood as primarily factual stories. They were designed to help people negotiate the obscure regions of the psyche, which are difficult to access but which profoundly influence our thought and behaviour ... When Freud and Jung began to chart their scientific search for the soul, they instinctively turned to these ancient myths. A myth was never intended as an accurate account of a historical event; it was *something that had in some sense happened once but that also happens all the time*.¹⁷⁷

In other words, myths were archetypal, not incidental, truths, reflecting eternal patterns that we could recognise, but which could not, without

diminishment, be translated into the everyday terms of *logos*. And, as Armstrong goes on to emphasise, myths were not primarily propositional, but grounded in action. The truth of a myth was not verified by data, but in the playing out of one's life:

The only way to assess the value and truth of any myth was to act upon it. The myth of the hero, for example, which takes the same form in nearly all cultural traditions ... showed us how to live more richly and intensely, how to cope with our mortality, and how creatively to endure the suffering that flesh is heir to. But if we failed to apply it to our situation, a myth would remain abstract and incredible.

However, things were slightly more complex than this suggests, since *logos* and *mythos* went through a number of transformations.¹⁷⁸ At one stage, indeed, according to the historian of ideas Bruce Lincoln, it was *logos* that was thought of as unreliable, feminine and seductive:

the most ancient texts consistently use the term *logos* to mark a speech of women, the weak, the young, and the shrewd, a speech that tends to be soft, delightful, charming, and alluring, but one that can also deceive and mislead.¹⁷⁹

'Words, words, words ...' This would certainly fit with Mercier and Sperber's view that logic was invented in order to win arguments, not to take us closer to the truth.

Mythoi by contrast were the ideals of men of action, weighty, performative, supportive of the truth: *alēthea mythēsasthai* ('to speak the truth') occurs as a formula five times in Homer, Hesiod and the *Homeric Hymns* (all prior to the end of the seventh century BC). *Mythoi* can at times be corrupt, but when they are, the effect is shocking and implies shame, such as if a lawyer were to lie; whereas the corruption of *logos*, at this stage, was taken for granted: 'the lying *logos* is deceptive, disingenuous and slyly delivered, hard to detect, the more to be guarded against'.¹⁸⁰

It's worth noting that *mythos* is inclusive of *logos*, whereas *logos* is exclusive of *mythos*. *Mythos* 'denotes the whole package, the *logos* plus the

speaker and the context; when *mythos* is in play, something is at stake'.¹⁸¹ It is thus dependent to an extent on trust in the authority of the speaker: as soon as people routinely question the authority of heroic figures, it loses power. Thus it is that with Plato one sees a reversal of the fortunes of *mythoi*. He cites them generally unfavourably in respect of their truth in numerous places, though he concedes there is 'some truth' in them.¹⁸² In reality, he is himself the inventor of several of the best-known myths of ancient philosophy: the myths of Atlantis, of Er's journey into the afterlife, of the ring of Gyges, of the chariot of Phæthon, not to mention the myth of the Cave.¹⁸³ Plato was complex. However, his legacy has been one-sided; and from this point onwards, truth is no longer thought of as that which comes from the experience of living, but as what can be argued towards without reference to context. Such a view is a necessary counterpoise, and can be productive: but as always, there needs to be a balance.

It will be obvious to the reader that *mythos*, in its trans-linguistic, implicit, richly connotative, performative way, rooted as much in the body and emotion as it is in cognition, is more amenable to the right hemisphere's take on the world; whereas *logos*, at least in Plato's sense – Heraclitus, for example, had used *logos* to mean a deep understanding *beyond language*, never to mean rationality or rhetoric – is more amenable to the explicit, linguistic, propositional stance of the left hemisphere. We now live in a world where *mythos* has been largely routed, and confined to the fiction shelves. Yet we need to bear in mind that there is more truth about the human predicament in *King Lear* than in any number of textbooks of genetics, irrespective of whether there was ever a King Lear at all.

This distinction between *logos*, the literal and the essentially decontextualised, on the one hand, and *mythos*, the metaphorical and essentially contextual, on the other, is not only grounded in, but maintained by, the difference between the two hemispheres. Most knowledge is not, after all, propositional in nature: it's just that when we look where the spotlight is, that's what we find. We have seen that all the aspects of language that are peculiarly important to poetry – not just metaphor, but implied meaning of every kind – humour, irony, connexions between ideas not normally approximated, the connotative power of symbols, the 'music' of language (the movement of the verse, its ictus, metre and rhyme) – are all preferentially mediated by the right hemisphere. By common consent

over generations, it is poetry which enshrines our profoundest insights into reality. ‘Language halts behind intuition’, wrote Whitehead:

The difficulty of philosophy is the expression of what is self-evident. Our understanding outruns the ordinary usage of words. Philosophy is akin to poetry. Philosophy is the endeavour to find a conventional phraseology for the vivid suggestiveness of the poet.¹⁸⁴

Other philosophers such as Wittgenstein (‘philosophy should be written only as one writes *poetry*’),¹⁸⁵ Heidegger (‘all philosophical thinking, and precisely the most rigorous and most prosaic, is in itself poetic, and yet is never poetic art’),¹⁸⁶ and Whitehead (‘philosophy is akin to poetry’)¹⁸⁷ came to believe that philosophical discourse needed ultimately to have the quality of poetry, as Schopenhauer believed it needed to have the quality of music.

Music is the non-literal form of communication *par excellence*, reliant entirely on metaphorical meaning experienced in the physical frame of the hearer. Music and song are of fundamental importance in human relationships and societies, in bonding at work, in recreation and in worship. There is no known society in which music does not play a pivotal part and in which it is not also thought of as a medium through which one may contact the divine.¹⁸⁸ Birds use song to attract mates, but it is only humans that can synchronise the rhythm, or blend the pitch, of their utterances with that of their fellows. Human music is not, like birdsong, thought to be largely individualistic in intention and competitive in nature (birdsong, like other instrumental utterances, is grounded in the left hemisphere, not, like human music, in the right; *perception* of birdsong by birds, however, is grounded in the right hemisphere).¹⁸⁹ Everything about human music suggests that its nature is sharing, non-competitive.¹⁹⁰ It is the means of group bonding: for good or ill; the communal ‘we’ is also emotionally bound up with song and performance. In all known societies there are acts of communal, synchronous speech and song, in chants and prayers, which recruit right hemisphere regions associated with empathy, and are independent of those implied specifically in the generation and interpretation of language and music: it also seems that in such activities we

do not experience what is said or sung as coming from ourselves, but as being communal utterances.¹⁹¹ There is a continuity in form and function with early poetry in preliterate societies, which was usually accompanied by music, was socially performative, and helped establish and expand common mythologies and narratives, confirming meaning in the deep structures of life, and consolidating the common purpose of the group: *mythos* at work.

Propositional discourse is limited in its ability to approach ultimate reality. Its very terms take us back, as left hemisphere discourse always does, to the familiar. In Nietzsche's phrase, 'language makes the uncommon common'. Philosophical language *requires* a metaphoric and flexible character and thus, according to Whitehead, 'philosophy in its advance must involve obscurity of expression, and novel phrases'.¹⁹² He claims that the history of ideas should be studied with a 'constant remembrance of the struggle of novel thought with the obtuseness of language'.¹⁹³ He later adds that one of the two main problems of philosophy is the 'uncritical trust in the adequacy of language'.¹⁹⁴ Although language is indeed the tool required for philosophy,¹⁹⁵ it is nevertheless a limited servant that should never become the master.¹⁹⁶

However, the rich ambiguity of meaning understood by the right hemisphere is seen by the left hemisphere only as a failing, a lack of precision: it sees there only obfuscation, or at worst, lies. The left hemisphere may add – and it adds enormously much – but what is added must be returned to the world that is grounded by the right hemisphere, or we misconceive the nature of reality. John Quijada, a *Star Trek* fan who studied symbolic logic (the predicate calculus) at university, and whose 'philosophical inclinations are toward an objective/realist philosophy', has invented a language, Ithkuil, which he describes on his website as 'an idealized language whose aim is the highest possible degree of logic, efficiency, detail, and accuracy in cognitive expression via spoken human language, while minimizing the ambiguity, vagueness, illogic, redundancy, polysemy (multiple meanings) and overall arbitrariness that is seemingly ubiquitous in natural human language.' No-one speaks Ithkuil, you will not be surprised to learn. Even its creator takes

up to ten minutes to translate a simple sentence ... much longer if new word-roots/stems are required, as the creation of roots takes

careful thinking and planning ... Long complex sentences can take up to half an hour. It then takes another five to fifteen minutes to look up the rules for writing the sentence in the script depending on the length of the sentence.¹⁹⁷

An artificial language is like an artificial flower – it has no roots: it can teach us nothing. As Heidegger put it, it is not so much that we speak language, but that language, the storehouse of generations of experience, speaks in us. Without the historical perspective of a lived language, we enter a hall of mirrors where our thoughts are simply reflected back to us, without all that penumbra of meaning, tiresome and inexplicable as it may seem to some, that is ‘seemingly ubiquitous in natural human language’. An artificial language is like Hans Christian Andersen’s clockwork nightingale – perfect in its way, unlike the living bird, but meaningless. We tire of the man-made, but not of that which shows human influence, such as a beautiful landscape lived in for generations, the result of civilisation working in harmony with what Pope called the ‘genius’ – the spirit – of the place. A language is like such a landscape, and the languages of different countries, like their terrain, offer different views of the world. Again, we need both to contribute; whereas it is the tendency of the left hemisphere point of view, unlike the right, to want the field to itself.

Myths also have this quality, like language itself, that they do not just derive from one mind alone but from a shared consciousness that stretches over time and place, and are not even consciously – *cannot* be consciously – conceived. The great anthropologist Claude Lévi-Strauss mystified some of his more literal-minded Anglophone colleagues by saying: « *Les mythes se pensent dans les hommes, et à leur insu ... d’une certaine manière, les mythes se pensent entre eux.* » ¹⁹⁸ In other words, it is not that we think up, or think in, myths, but that myths ‘think themselves’ in us all, without our being aware of it, and even in some sense think themselves into being on their own. As Lichtenberg warned, ‘the metaphor is far cleverer than its author, and so it is with many things. Everything has its depths.’¹⁹⁹

We know that the mind is not a *tabula rasa*, a blank slate on which experience inscribes itself from scratch, but comes, as it were, prepared for the encounter it is to have with the forms of the world, including, but by no means limited to, the forms of language. To take a very simple example, the structure of the visual cortex comes fitted and prepared for interpreting the

principal physical shapes and their elements that it will encounter in the world. But that is only a very simple example. What is true of language may be true of the forms of myths, which are remarkably consistent and persistent in space and time: something like Jung's collective unconscious may be acting by means of epigenetics, or by means we may as yet be able only to surmise. The mathematician and logician CS Peirce wrote that 'it is somehow more than a mere figure of speech to say that nature fecundates the mind of man with ideas which, when those ideas grow up, will resemble their father,' – or, as I would prefer to say, mother, – 'Nature.'²⁰⁰

Nowadays our unthinking reaction is to reject any belief or experience whose origins are not known to us: unless we are fully conscious of everything about it and have it under control, it is treated as suspect. But one of the most important aspects of many experiences – such as the experience of love, of art of every kind, of the magnificence and beauty of the natural world, of ancient myths and narratives, of the solemnity of a religious ritual or of an ancient tradition – is that they require us to relinquish control. They speak of something much bigger than us, that cannot entirely be articulated; something ancient and enduring, which speaks, if it can be said to speak at all, *through* us, not just *out* of us. It is an eternal drama in which we each play a humble, but by no means insignificant part – no longer merely in the desolate limelight of our own story, signifying nothing, and reduced to strutting and fretting our hour upon the stage, only to be heard no more. The beauty and power of art and of myth is that they enable us, just for a while, to contact aspects of reality that we recognise well, but cannot capture in words. It is precisely their multi-layered, sometimes paradoxical meaning, well beyond articulation, that gives them value, and makes them resonate with us at so many different levels and in so many different ways.

The more important something is, the more we have to struggle in the attempt to reduce it to language. We would be lost without words, but sometimes it is wisdom to be lost *for* words. Words are always a representation in terms of something else. The work of art exists precisely to get beyond representation, to *presence*, even if that presence is itself composed of words, as it is in poetry. If this were not so, a lot of effort could have been spared, as it could all have been better stated in prose. The work of art does not hide, represent, or body forth something *else*, that must therefore be decoded: it is precisely what it is. And yet neither is it opaque,

as though we were stopped at its frontiers. It is *semi-transparent*, translucent: we see it all right, and yet see *through* it to something beyond.

‘By the way’, said Goethe, ‘the Germans are an odd lot’:

They come and ask what idea I was trying to embody in my *Faust*, as if I knew that myself and could articulate it! ... I am rather of the opinion that with poetic productions the more unparalleled, and the harder for reason to grasp, the better.²⁰¹

Many languages have distinct words for knowing, dependent on the sense in which one can be said to know. In Latin *sapere* is distinguished from *cognoscere*, in French *savoir* from *connaître*, in German *wissen* from *kennen*. In each case the first indicates propositional knowledge, ‘knowing *that*’ such and such is the case, which requires no experience; while the second indicates knowledge *of* someone, some place, or other unique aspect of the world, directly from experience. Ultimately, in fact, all knowledge derives from experience, for which there are no propositions – thus *sapere* bows to *cognoscere*, *savoir* to *connaître*, *wissen* to *kennen*, propositional knowledge to knowledge by encounter. When we say we know something, what we mean is that we see that it is like something else that we reckon we already know better, from a previous encounter. And those ‘somethings else’, followed far enough, return us in every case to embodied experience.

What we are talking about here is a type of essentially *metaphorical* understanding, of which myth, poetry, drama and ritual are all manifestations. In true metaphor the intention must remain implicit; spelling it out causes its richness and emotional impact to collapse, much as explaining a joke makes it fall flat, or paraphrasing a poem reduces it to a series of banalities. It returns us from the ‘presencing’ of the world in language (right hemisphere) to its ‘re-presentation’ in language (left hemisphere). We do not use metaphor to decorate, and therefore obscure, something best conveyed literally (although that would be how the left hemisphere sees it), but to bring to life a deeper and broader set of meanings than could be conveyed by literal language. ‘It would be more illuminating’, writes Max Black, ‘...to say that the metaphor creates the similarity than to say that it formulates some similarity antecedently existing.’²⁰²

All understanding whatsoever is, at bottom, metaphorical. It is not that there is, as *per* Locke, a bed of literal truth, on which metaphorical truth, like a colourful counterpane, is overlaid. It is the other way round. Metaphor is where, as Wittgenstein put it, one's spade reaches bedrock and is turned. Literal truth is something just further removed from experience, taken into the realm of the 'literal', ie, that of letters. Everything has to be expressed in terms of something else, and, as I say, those something elses in language eventually come back to bodily experience. There is nothing more fundamental in relation to which we can understand *that*.

Even words like 'immaterial', 'insubstantial', 'abstract' and 'virtual' refer ultimately to embodied experience. Immaterial comes from the Latin *materia*, meaning 'wood', and even further back, from *mater*, 'mother', in the sense of an origin: the immaterial is that which has no mother. 'Insubstantial' comes from Latin, *sub-*, under, + *sistere*, to 'stand firm': thus something that has nothing standing under it. 'Abstract', as mentioned earlier, is from Latin *abs-*, away, + *trahere*, to 'drag': something that has been dragged away from its 'context' (itself from Latin *con-*, together, + *texere*, to 'weave', ie, 'that which has been woven together'). 'Virtual' comes by a roundabout route from Latin *virtus*, the 'strength of a man' (*vir*). And 'literal' itself? It comes, via Latin *littera*, from a Sanskrit root *li*, indicating something 'daubed' or 'smeared': that's what letters are, after all.

As Lakoff and Johnson point out,

metaphor is centrally a matter of thought, not just words. Metaphorical language is a reflection of metaphorical thought ... Eliminating metaphor would eliminate philosophy. Without a very large range of conceptual metaphors, philosophy could not get off the ground. The metaphoric character of philosophy is not unique to philosophic thought. It is true of all abstract human thought, especially science. Conceptual metaphor is what makes most abstract thought possible. [203](#)

I will come on to the question of whether ultimate reality can be expressed in words at all. By their own accounts, physicists (like mathematicians) tend to think in visual images: to try to appreciate or understand mathematics without visualising it, as physicist Tristan Needham suggests, is like trying to understand music from the score in a

culture where it is forbidden to play or hear it.²⁰⁴ But whenever physicists do express themselves in language, the language is highly metaphorical. One could say the same of spiritual insight: words betray it.

According to Bryan Magee,

direct experience which is never adequately communicable in words is the only knowledge we ever fully have. *That* is our one and only true, unadulterated, direct and immediate form of knowledge of the world, wholly possessed, uniquely ours. People who are rich in that are rich in lived life. But the very putting of it into words translates it into something of the second order, something derived, watered down, abstracted, generalised, publicly shareable. People who live most of their outer or inner lives in terms that are expressible in language – for example, people who live at the level of concepts, or in a world of ideas – are living a life in which everything is simplified and reduced, emptied of what makes it lived, purged of what makes it unique and theirs.²⁰⁵

However, the connotative aspects of language, all that language implies rather than states explicitly, help us get back in touch with the world as the right hemisphere experiences it. ‘The metaphor is perhaps one of man’s most fruitful potentialities’, wrote Ortega y Gasset: ‘its efficacy verges on magic, and it seems a tool for creation which God forgot inside one of His creatures when He made him.’ Metaphor embodies thought and places it, where it belongs, in a living context. In this, it bridges the gap between language and the world, a gap entailed on us by the very nature of language. As philosopher Jan Zwicky puts it, ‘metaphorical language depends on non-metaphorical language the way the art of healing depends on the presence of injury and disease.’²⁰⁶

This is why poetry (which arose historically *before* prose) is so vital to an understanding of the world. Its new conjunctions, its metaphors, its tone, its musical aspects, are all – like music, for most of us – appreciated by the right hemisphere. But in day-to-day speech it is also the right hemisphere that ultimately makes sense of language, and understands an utterance as a whole, in context, with all its non-literal, implicit meaning.²⁰⁷

‘Some words and sentences’, according to the famous literary critic IA Richards,

do seem to mean what they mean absolutely and unconditionally. This is because the conditions governing their meanings are so constant that we can disregard them ... In weighing out a pound of tea we can forget about the mass of the earth. And with words which have constant conditions the common sense view that they have fixed proper meanings, which should be learned and observed, is justified. But these words are fewer than we suppose. Most words, as they pass from context to context, change their meanings; and in many different ways. It is their duty and their service to us to do so ... ²⁰⁸

He called the belief that a word has an ideally single meaning of its own, which dictates the purpose for which it should be uttered, the Proper Meaning Superstition. Unfortunately, when we forget that the stability we think we see depends wholly on the context always remaining constant – as, according to Richards, we commonly do – what is a reasonable practical shorthand assumption becomes a superstition that blocks our understanding. When we think about the world – or time, space or God – and try to make sense of it, we are, precisely, not in those everyday contexts: that’s where the idea of fixed meanings leads to false reasoning.

Recognising this is not a call to abandon rigour, but to embrace it fully. Without a language one can rely on, there is no way of establishing common truths. But a language that is not sensitive to context is dangerously unreliable. You can read a clock precisely, but you can rely on what it says only if the hands are moving in synchrony with the world. A stopped clock is always dependably the same, but almost always dependably wrong. Using language as accurately and clearly as one can (but not a whit more) is to be a custodian of truth in an age where language often seems to be floating free of its moorings in the real world.

Good metaphors are like good jokes: they rely on making unusual connexions. As Zwicky says, ‘Surprise is common to good metaphors and good jokes ... Seeing [a weak metaphor] requires no leap of imagination.’²⁰⁹ A metaphor fails if it is too familiar. Its energy dissipates

immediately and it dies. We no longer see the gap that is overcome. The two parties are either so remote that no 'electrical connexion' can take place, or so close that none is required: in either case, no *leap* of imagination takes place.

Mythos, relying on implicitness, can be responsive and responsible: inextricably bound up with its reception in the mind of the one who hears or sees, it is itself changed by that reception. Relying on explicitness, *logos* is unidirectional: it drives a line of argument, it declares 'how things are', and by so doing aims to fix them. Each has its uses. But note that in metaphor nothing can remain unchanged by the interaction, which is bi-directional, reverberative. When we call a man a wolf, we don't just make the man more wolf-like, but the wolf more human. All knowledge, as Bateson once said, is knowledge of difference – except that it is knowledge of difference within sameness, and sameness within difference: it is only when we see both the sameness and the difference that we can say we know something. Each implies the other. And a metaphor, ultimately the only way to come by knowledge, is an *equal* drawing together of two things in which neither can escape being changed by the encounter.

I may seem to be making too much of this, but the point is important. We think that connexions are causative and temporal, running one way. *Logos* suggests as much. As if to make the point, Lakoff and Johnson, in their book *Philosophy in the Flesh*, in which they establish beyond doubt the grounding role of metaphor in understanding, nonetheless write: 'Does the metaphor fit a pre-existing qualitative experience, or does the qualitative experience come from conceptualising what we have done via that metaphor?'²¹⁰ Surely, neither. This is the old temporal causation problem: in reality it's not a linear relationship, but a betweenness. There is a never-ending reverberative loop set up between the experience and the metaphor, in which neither can be said to have precedence. It is not one of steps, or progress by parts, but one of the co-creation of a new whole.

Coleridge refers to two ways of arriving at truths: sequential, stepwise understanding, in which, as it were, one focusses on one's feet, contrasted with the cultivation of a love for the subject which enables an imaginative seizure of the whole as one steps toward it. Describing how his father introduced him to astronomy as a child, Coleridge writes that he heard him speak of astounding matters far beyond everyday experience without the

least ‘incredulity’, because he was already familiar with tales of the imagination:

my mind was habituated to the Vast – & I never regarded my senses in any way as the criteria of my belief ... I know no other way of giving the mind a love of ‘the Great’, & ‘the Whole’. – Those who have been led to the same truths step by step thro’ the constant testimony of their senses, seem to me to want a sense which I possess – They contemplate nothing but *parts* – and all *parts* are necessarily little – and the Universe to them is but a mass of *little things*.²¹¹

Is it possible to combine ‘knowledge about’ (*savoir/wissen*, the stepwise understanding of the parts) with ‘knowledge of’ (*connaître/kennen*, the awe-inspiring encounter)?

The intellect is ‘incurably abstract’, as CS Lewis says, while experience is intrinsically concrete. How can we have both kinds of knowledge at once – knowledge about, and knowledge of?

You cannot *study* Pleasure in the moment of the nuptial embrace, nor repentance while repenting, nor analyse the nature of humour while roaring with laughter. But when else can you really know these things? ‘If only my toothache would stop, I could write another chapter about Pain.’ But once it stops, what do I know about pain?²¹²

Lewis carries on to suggest that in fact this is the whole purpose of myths. In them we see otherwise abstract truths more clearly, at the very same moment that the experiential reality is brought home to us. The implicit nature of myth, which must never be made explicit, permits it to embody something that, once it is looked at directly, turns into a wraith: it collapses into an abstraction.

The understanding yielded by *mythos* is not an optional extra, a dispensable add-on, an embellishment; but foundational, non-negotiable. It is something intrinsic to our ability to situate ourselves in the world, and to live a fully human life. We become sick without it: ‘mere purposive

rationality’, wrote Gregory Bateson, ‘unaided by such phenomena as art, religion, dream and the like, is necessarily pathogenic and destructive of life.’²¹³ Again I hear Darwin’s poignant complaint that his mind had become a machine for grinding out facts; and that ‘the loss of these tastes is a loss of happiness, and may possibly be injurious to the intellect, and more probably to the moral character, by enfeebling the emotional part of our nature.’

In truth, we are never without a *mythos* of a kind. In the absence of the celebration of the timeless *mythoi* given us through art and religion, we do not avoid espousing myths of our own making, much impoverished though they must inevitably be: nowadays they are those of the Mindless Machine and of the Selfish Gene.

Louis Sass points out that Wittgenstein saw greater wisdom in mythic than in scientific accounts of the world, which ‘give us the illusion of explaining a world that we would do better to wonder at’.²¹⁴ And he compares Wittgenstein and Freud:

Though [Wittgenstein] is in many respects the deeper sceptic of the two, his is a curious scepticism, profoundly dubious about doubt itself and peculiarly sympathetic to belief. Wittgenstein, who had been trained as an engineer, wrote that he himself found scientific questions interesting, but never really gripping. Hypotheses, cause and effect relationships, even the sorts of insight psychoanalysis could offer: in his view, none of these could address the truly significant issues or existential dilemmas of our lives ... Wittgenstein believed, in fact, that the causal and scientific understanding so prominent in our age often had the insidious effect of *concealing* important questions – by giving a false sense of inevitability and turning us away from the richness and multiplicity of the world. ‘People who are constantly asking “why”’, he wrote, ‘are like tourists who stand in front of a building reading Baedeker and are so busy reading the history of its construction, etc., that they are prevented from *seeing* the building.’²¹⁵

(So *that* was what people did to shield themselves from reality before the invention of the iPhone.)

Knowledge *about* displaces knowledge *of* the world. What we see comes to be our representation of reality, in which there are *things* that we have to learn how to connect, not relationships out of which what we subsequently call ‘things’ emerge. Evelyn Underhill saw how labels become more real than the reality they try to represent, and how such a world is inevitably not just re-presented, but *mis*-represented:

Because mystery is horrible to us, we have agreed for the most part to live in a world of labels; to make of them the current coin of experience, and ignore their merely symbolic character, the infinite gradation of values which they misrepresent. We simply do not attempt to unite with reality. But now and then that symbolic character is suddenly brought home to us. Some great emotion, some devastating visitation of beauty, love, or pain, lifts us to another level of consciousness...

And then it is that we see beyond the ‘neat collection of discrete objects and experiences’ which we have got used to calling the world.²¹⁶

Among the beneficial effects of art and religion at their best are to keep us from wandering aimlessly in this deserted landscape. Jürgen Habermas, formerly unaccommodating of religion, has come to believe that religion must play a large and indispensable part in society:

Among the modern societies, only those that are able to introduce into the secular domain the essential contents of their religious traditions which point beyond the merely human realm will also be able to rescue the substance of the human.²¹⁷

Clearly Habermas is speaking not of the propositional element in religion, but of the *mythos*. Propositions, however intricately devised, are the work of *logos*, and merely get in the way of the process of religion, which is, or should be, about how to find meaning and fulfilment in life, and to help us understand our relationships with one another, with the world at large, and with the divine, however we conceive it.

One important difference between *mythos* and *logos* is that, according to *logos*, knowing how or why something happens appears to exhaust its

nature; whereas according to *mythos*, the nature of something is precisely what cannot even be approached by *logos*. In talking about art, neuroscience seems satisfied with describing mechanisms of perception and offering reductionist accounts of human preference. But it's not just a matter of *preferring* something, like mint toothpaste or a type of handbag. It's not even a matter of accounting for beauty or pleasing emotions, since art cannot be reduced simply to either of these. Philosopher of neuroscience Alva Noë writes in relation to work on the mechanisms of perception:

Some of us might wonder whether the relevant question is how we *perceive* works of art, anyway. What we ought to be asking is: *Why do we value some works as art? Why do they move us? Why does art matter?* ... Far from its being the case that we can apply neuroscience as an intellectual ready-made to understand art, it may be that art, by disclosing the ways in which human experience in general is something we enact together, in exchange, may provide new resources for shaping a more plausible, more empirically rigorous, account of our human nature.²¹⁸

In other words *mythos* is required to help us situate *logos*, not the other way round; since, about *mythos*, *logos* has plentifully little to say. 'Myth is the isthmus which connects the peninsular world of thought with that vast continent we really belong to', writes Lewis.²¹⁹ 'It is not, like truth, abstract: nor is it, like direct experience, bound to the particular.' And he continues, refining its relationship with truth: 'What flows into you from the myth is not truth but reality (truth is always *about* something, but reality is that *about which* truth is), and, therefore, every myth becomes the father of innumerable truths on the abstract level.'²²⁰

The ancient myth of Orpheus and Eurydice has a deep meaning that is relevant to one thread that winds its way through this entire book. Let me remind you of the story in outline. Orpheus was a demigod, his mother being one of the Muses and his father a Thracian prince. His mother gave him the gift of music, and he grew to be such an incomparable musician that all things, both animate and inanimate, were drawn to his lyre. He could move animals and trees, but also rocks and stones, and even alter the course of rivers, by the power of his music alone. He loved a nymph called

Eurydice: and they married. But shortly after the wedding, while she was walking in the fields with her bridesmaids, she was bitten by a viper, and died. Heartbroken, Orpheus resolved to go down into the underworld to rescue her; there he was summoned to the presence of the gods. After pleading his case, he sang, and the gods were so moved that they relented, and acquiesced to his request to take his bride back, though on one condition: that he must not look directly at her while he was leading her out to the upper world again. So he stepped ahead of her on the ascent, and she followed; but at the last minute, when they were almost at the mouth of the cave that led out of the underworld, he could contain himself no longer. He turned and looked at his bride. With cries of joy he ran to embrace her, but she vanished before his eyes, and was drawn back to the underworld, never to be seen by him again.

This is not only, in my view, probably the greatest of the Greek myths, as an account of love, its mysteries and its losses, but is itself an account of *the nature of myth*, as CS Lewis pointed out:

In the enjoyment of a great myth we come nearest to experiencing as a concrete what can otherwise be understood only as an abstraction. At this moment, for example, I am trying to understand something very abstract indeed – the fading, vanishing of tasted reality as we try to grasp it with the discursive reason ... But if I remind you, instead, of Orpheus and Eurydice, how he was suffered to lead her by the hand but, when he turned round to look at her, she disappeared, what was merely a principle becomes imaginable. You may reply that you never till this moment attached that ‘meaning’ to that myth. Of course not. You are not looking for an abstract ‘meaning’ at all. If that was what you were doing, the myth would be for you no true myth but a mere allegory. You were not knowing, but tasting; but what you were tasting turns out to be a universal principle. The moment we state this principle, we are admittedly back in the world of abstraction. It is only while receiving the myth *as a story* that you experience the principle concretely. ²²¹

It makes us feel, as nothing else could do, the dangers of explicitness, and therefore the value of obliqueness: of myth, intuition, poetry, music, and all the other arts, true philosophy, true spiritual understanding, and

every imaginative act whose aim is to offer a glimpse of the elusive nature of reality, not to mention the power of all that body of tacit knowledge without which we begin to lose life. It is the natural counterpoint to the myth of Prometheus, which similarly warns of equally problematic tendencies of the left hemisphere's disposition towards the world: striving to know far more than the human mind can understand, and to control far more than it should, if it is wise, attempt to control. And, once again, if you don't see why, I cannot help you, because if I attempted to grasp its 'meaning' any more firmly and drag it into the light, it would vanish and die.

CONCLUSION

The idea of reason has at least two main meanings: a rigid, abstract, linear mode, prizing precision and certainty, and owed to the left hemisphere; and an embodied ability to hold in suspension knowledge of various kinds justly, and to evaluate them in the context of lived experience, where reason is not in any sense at war with feeling or imagination. This mode is more dependent on the right hemisphere: and is, like the right hemisphere's understanding of science, in my view more fruitful than the alternative that is often served up in its place. And it is vanishing and dying.

LOGICAL PARADOX: A FURTHER STUDY IN LEFT HEMISPHERE CAPTURE

The evil and thus keenest danger is thinking itself.
It must think against itself, which it can only seldom do.

—*Martin Heidegger*¹

THERE IS A PARADOX ENTAILED IN PARADOX. WHAT WE CALL PARADOX IS seen by the purely analytic mind as a sign of an error somewhere – an error which it may be hard to identify, but which nonetheless exists, and must be flushed out and exposed, no doubt by further analysis. Meanwhile, to the imaginative mind it may be a sign of quite the opposite: that we are at last approaching, in one of two possible senses, a deeper level, not of error, but of truth.

The first sense is this: that in the deep (though, clearly, not the superficial) structure of reality opposite truths do actually coincide, and we must therefore accept both. Such a view can be found in, for instance, the writings of Heraclitus and Empedocles, and in the philosophical literature of China and India for millennia; and it was given memorable expression in our own time by the ‘father’ of modern physics, Niels Bohr: ‘it is the hallmark of any deep truth that its negation is also a deep truth.’² I will come to this important topic in the first chapter of Part III, in which I consider the coincidence of opposites. Note that such a realisation does not leave us logically adrift, so that we have to accept that any statement and its opposite must be true. Bohr makes an important distinction: everyday truths

do not give rise to paradox, deep truths do. ‘One of the favourite maxims of my father’, wrote his son Hans Henrik Bohr,

was the distinction between the two sorts of truths, profound truths recognized by the fact that the opposite is also a profound truth, in contrast to trivialities where opposites are obviously absurd.³

Either I had milk in my coffee this morning or I didn’t, but a particle may also be a wave. So far, so good. But what is the second sense? This concerns the structure of the mind and brain: the distinct versions of the world made possible by either hemisphere. As the reader is aware, these have complementary, but contradictory, properties. If, as the philosopher Nicholas Rescher puts it, a paradox is ‘a set of mutually inconsistent propositions, each of which seems true’,⁴ that may be because of differences between the ways in which the right and left hemisphere experience the world. I believe, in fact, that many, if not all, logical paradoxes can be seen as arising from the left hemisphere’s attempt to analyse something that is better grasped as a whole by the right hemisphere. Which is why, unlike insight into the coincidence of opposites, such paradoxes leave us, not illuminated, but puzzled. We *know* that Achilles can overtake the tortoise, yet the more we think about it the more impossible it seems. Much philosophy concerns itself with such paradox. ‘One must not think ill of the paradox’, wrote Kierkegaard with a hint of his characteristic mischief, ‘... the thinker without a paradox is like the lover without passion: a mediocre fellow’.⁵

It is this form of paradox I wish to look at in this chapter: the product of the left hemisphere’s attempt to grasp analytically what the right hemisphere intuitively understands. By such an approach, I hope to generate a new perspective, and perhaps cast some light. And often, as I hope to show, we find evidence of more than one aspect of hemisphere differences operating at once in the same paradox, fitting together coherently, and thus strengthening the argument for the relevance of a hemispheric approach.

In what follows I am not offering ‘solutions’ to the paradoxes I discuss. I am merely pointing out how a hemispheric viewpoint helps to show why they arise. It is worth noting that, according to philosopher Margaret

Cuonzo, as far as the deeper paradoxes go, at least, ‘not much in the way of progress has occurred’.⁶ So *any* light might, I hope, be welcome light.

UNEQUAL TRUTHS

Though I suggest that paradox arises from two conflicting views, each of which has a claim on truth, I will argue that that does not entail the simple conclusion that they have equal claims. If you are uncomfortable with unequal truths, thus with degrees of truth – ‘surely, either it is true or it isn’t?’ – you will be particularly susceptible to being baffled by paradoxes, since one of the many elements that give rise to paradox is, precisely, that there are degrees of truth: not all truths are created equal. This has consequences for apparent contradiction, since a statement and its denial can often be true in different degrees and different contexts. Such thinking is dependent on the right hemisphere: black and white thinking, as you remember, is a predilection of the left hemisphere. Let us have a look at some of the paradoxes that involve such an element, and see what other hemispheric elements they contain along with it.

A number of paradoxes depend for their status as paradoxes primarily on an inappropriate lust for precision. I have mentioned the Quine-Duhem Paradox.

- *Quine-Duhem Paradox.* No hypothesis can be tested in isolation from an indefinite set of auxiliary hypotheses; in order to show that a hypothesis is mistaken, it is necessary to isolate that hypothesis from its set of auxiliary hypotheses; therefore, no hypothesis can be shown to be mistaken.

But conviction comes by degrees. The perception that an apparently mistaken hypothesis might in fact be correct, if we were only prepared to question one of the many auxiliary hypotheses that surround and support it, is hugely important, and is constantly overlooked. But that doesn’t mean that we cannot often be reasonably sure whether a hypothesis is mistaken.

One answer to uncertain situations is to adopt what is known as a Bayesian approach, after an eighteenth-century mathematician and probability theorist, Thomas Bayes. In essence, this involves a sophisticated mathematical estimate of the change in probability added by the new evidence, obtained by contrasting ‘prior probability’ (before taking into

account the new evidence) with ‘posterior probability’ (after taking the evidence into account). Although there is precision to the formula, there is an inevitable lack of precision to the estimate of prior probability, which is based on one person’s idea of the strength of a belief that varies from person to person, and within the same person from moment to moment. Purported accuracy is only as valuable as the accuracy of its antecedents.

Related to the Quine–Duhem Paradox is the Sceptical Paradox.

- *The Sceptical Paradox.* I can know for sure that I am in London only if I can know that I’m not dreaming; I cannot know that I’m not dreaming; therefore, I cannot know for sure that I am in London.

An answer to this is to interpret what counts as knowledge in context, an approach known, indeed, as ‘contextualism’. It entails acceptance of the fact that if you set the bar high enough, we can never be said to know anything. Knowledge is a matter of degree: our standards for ‘knowing’ anything change with context. Demonstrating an everyday matter such as that I am now in London does not demand tiresomely high standards of evidential confirmation. However, proving that I am not dreaming may require such a high standard of evidential confirmation that it cannot be achieved, and we will never know whether, in the words of the title of Calderón de la Barca’s famous play, *Life Is a Dream*.

You will recall William James’s words: ‘more than half the trouble that metaphysicians and logicians give themselves over the paradoxes and dialectic puzzles of the universe’ are due to abstraction from context.

Sensitivity to matters of *degree*, and to *context*, are both areas in which the left hemisphere is handicapped by comparison with the right. The Hedonic Treadmill refers to the fact that we adapt quickly to whatever circumstances we find ourselves in, and that pleasure comes from a *relative* difference of position between ourselves and others, or between ourselves now and ourselves in the immediate past, so that we can end up rich, but always, nonetheless, miserably searching for something further. It shows that pleasure is not attached to the possession of things that supposedly have absolute value (LH), but derives from the context of the web of life, according to which ‘things’ change their value constantly (RH). It is worth remembering that time is a context, and that the left hemisphere appears not

to understand time: this results in the neglect of one of the most important contexts we have. Let's take a look.

An interesting paradox concerns the Unexpected Examination (or, in another version, the Unexpected Hanging).

- *The Unexpected Examination.* A teacher announces to his class at the beginning of the week that at some point in the week he will submit them to an unexpected examination. Apparently this can never occur. This is because clearly it cannot take place on Friday, because by then, not having happened yet, it would be expected. But it can't take place on Thursday either, since this is now the last possible day, and so the same reasoning applies. Nor Wednesday for the same reason, and so on. Therefore it cannot happen at all.

The word 'unexpected' has two meanings here. One is 'unexpected at the moment it happens'; the other is unexpected at the time the announcement is made. The first type of unexpectedness changes in degree, and does so with context, as the week goes on, day by day: on Monday it is one in five, on Tuesday it is one in four, and so on. In other words it changes with time. According to this meaning, what is unexpected only becomes, in a sense, certain, once Thursday is past, and by then the term unexpected has done its work – and the *least* expected day, according to the left hemisphere, turns out to be the very day of the exam:

That day will have been unexpected all along. When it comes around it will, of course, no longer be an unexpected day, for what is now present is no longer unexpected. But the last day *cannot be dislocated from the other days at the time the announcement is made*, except by a kind of theoretical anticipation of actual history, and thus by moving away from the announcement of a possibility to that state of affairs where possibilities are specified and distinguished *one after the other*.⁷

The point being made here by the philosopher Paul Weiss is that the situation cannot be picked apart serially: it needs to be understood as a whole at a moment in time, the moment at which the announcement is

made. From this perspective the date is from the outset uncertain, and to be prepared means, however you look at it, being prepared every single day: whatever the left hemisphere tells you, you will be caught on the hop if you work out cleverly that there can't be an unexpected examination – and it then happens on Wednesday.

Another way to think of the paradox here is that it involves the degree to which imprecision is tolerated. If the teacher were to say 'there may or may not be an examination', the effect would be the same, but the paradox would not arise. The imprecision here has the effect of allowing the meaning of the word 'unexpected' to change with time, in other words with context, and therefore to be more accurate, if less precise. The left hemisphere finds it hard to accommodate such flexibility. A desire for an interpretation that is unambiguously correct at all temporal points lies behind much of the paradox literature, and once again illuminates the handicaps of a certain highly decontextualised, over-precise way of looking at the world. Such paradoxes are fun, but the fun derives from the awareness of how badly (what we can now see as) left hemisphere thinking leads us astray.

We have noticed that the days are picked off *serially*. Then we might notice that this has to be done starting at the end of the time period and working *backwards*. In other words we view the week a slice at a time; and we view it retrospectively, not prospectively as it is lived. For the time being, let us just note these elements – serial analysis and retrospection; their significance will be revealed as the argument unfolds.

Many paradoxes involve the breaking down of a flow into parts or slices. Of these, perhaps the most celebrated cases are the paradoxes of Zeno of Elea, a Greek philosopher of the fifth century BC. He is well known for paradoxes relating to time and space, often inviting the conclusion that motion is impossible. Zeno's paradoxes have tantalised ever since they were first formulated, and have been considered by some philosophers to be simply beyond solution.

- *The Dichotomy (or Division)*. Suppose you wish to leave the room. Before reaching the door you must get halfway there, and before that, a quarter of the way there, and before that, an eighth of the way, and a sixteenth ... and so ad infinitum. An infinite number of

steps cannot be accomplished in a finite time, so no motion is possible, and you are rooted to the spot.

One answer is that a convergent series of infinitely many parts may be contained within a finite number of any size you like. The infinite series $1 + \frac{1}{2} + \frac{1}{4} + \frac{1}{8} \dots$ does not sum to infinity, but to 2. The serial analysis of any given step you take is compatible with there being a finite number of steps between you and the door. The problem comes from thinking of infinity as the last in a series of escalating (or diminishing) numbers. But there is no last, and infinity is not part of a series.

The Dichotomy involves a number of elements, but among them there is a *retrospection*: one begins, conceptually, at one's destination and works backwards. This demands that the completed act must be posited at the outset, so that one can talk about its half, quarter and so on. It can be broken down retrospectively into pieces: it can be *analysed*. But it cannot be built up prospectively – that is to say, *created* – from pieces or slices of space or time. It can potentially be analysed *ad infinitum*, but it cannot be created *ad infinitum*. That in turn relates to the issue of wholes and parts: a given whole can be broken down, after the fact, into as many 'parts' as you like, but it cannot be put together from parts, not even as many as you like. That is because the parts, like slices of time or space, are a mental device only: they belong to a left hemisphere *representation*, or fiction. A finite distance is achieved in a finite number of steps: 'the illusion that it is infinite is due to mathematicians who confuse their mathematical *representations* with *what is represented*.'⁸ Or as I would put it for clarity's sake, who confuse the representation with the presence, the left hemisphere's take with that of the right.

This difference in time between the hemispheres – retrospection on something completed (in the left), as opposed to being present moving forward in an always-evolving process (in the right) – is of crucial importance, since what is at stake here is nothing other than the nature of time itself. Analysis is a (1) *fragmentation* into (2) *static* instants of a (3) 're'-presentation, by definition 'after' the fact and (4) *in an abstract realm*; it has all the hallmarks of the left hemisphere about it. By contrast our intuitive understanding takes as an (1) indivisible *whole* (2) the nature of *motion* as it is (3) *present* within (4) *embodied experience*, and has all the hallmarks of the right hemisphere about it.

Consider another space-time problem of a simple kind in which the emphasis is on space, rather than on time: that of how to construct a line. Extension is an irreducible element in our experience of both space and time. Once a line already exists, you can *retrospectively* locate a point in it; but you cannot make a line, *prospectively*, out of points, even an infinite number, since a point by definition has no extension. If you think of a point as a pencil dot, you are cheating, because the dot already possesses extension – it is, in effect, a short line – and you have just smuggled in the very thing you were trying to account for. Similarly a span of time cannot be broken down into instants, because the instant has no thickness. As soon as you allow it the least thickness, it is already a span of time, and you have just imported the element you were trying to account for by putting together instants. An infinity of points or instants will not get you to extension, because the nature of extension, or depth, requires a leap (as the left hemisphere would see it), to something of an irreducibly different nature.

This reminds me of a saying of Kierkegaard, which is invariably misquoted, truncated, and taken out of context, and therefore becomes a banality, to the effect that life is lived forwards but can be understood only backwards: in other words, we see what we were stumbling towards only with hindsight. But this is completely to misunderstand his point, which emerges if one looks at what he actually said in context:

It is perfectly true, as philosophers say, that life must be understood backwards. But they forget the other proposition, that it must be lived forwards. And if one thinks over that proposition it becomes more and more evident that life can never really be understood in time simply because at no particular moment can I find the necessary resting-place from which to understand it – backwards.⁹

He is talking about the rather less obvious point that philosophy *stops time* and *represents* it, retrospectively; whereas when we are living, we experience the world as it happens, in the flow of time. Thus it cannot be ‘understood’ in the sense used by analytic philosophers outside of time.¹⁰

I earlier referred to a closely related, and more famous, paradox of Zeno’s.

- *Achilles and the Tortoise*. The tortoise challenges the famously swift-footed Achilles to a race, and Achilles graciously gives the tortoise a good head start. But Achilles can never catch up with, never mind overtake, the tortoise, since first he must get to the place from which the tortoise started, but by then the tortoise will have moved on; so then he must reach the tortoise's new position, but by then the tortoise has moved on; and so *ad infinitum* ...

The problem here is effectively the same as in the Dichotomy: slicing a flow, seeing a whole as the sum of the parts, retrospectively on what in reality is over in a few seconds and a few strides, and thereby reducing it to segments – a *representation* from which the actual flow of time and movement, what Bergson called *durée*, has been removed, and cannot be recaptured. It is easy to kill something with a knife, but with the knife you cannot make it live again.

Time is represented, retrospectively, along a line, whether that is straight or curved; and it is along that line that time is measured, by taking the difference between two points. Every moment the clock points – at a point: a digital clock equally specifies a series of static points by naming them, however rapidly they succeed one another. But time is not made up of duration-less moments, any more than the line that represents it is made up of points. A point has *no* extension, whether in space or time: that is the whole point about a point.

Note that all the 'building blocks' of the experiential world – space, time, depth, and, I would add, consciousness – are clearly different in kind from anything else, are irreducible, and therefore require a leap: they cannot be approached incrementally. Motion, being reciprocally emergent with space and time, also requires a leap, and can't be crept up on gradually from stasis. There is in fact an ancient paradox, known as the Antinomy of Change, which was discussed by Plato and Aristotle. It both touches explicitly the paradox of how motion arises, and, at a second level, implicitly illuminates the need for what I call a leap in arriving at other irreducibles.

- *The Antinomy of Change*. Imagine an object at rest that then begins to move. At the instant when the movement starts, is it at rest or in motion?

The point is that this paradox applies to change of every kind, and his inability to find a satisfactory answer predictably led Parmenides to deny the existence of change (the world's first great exponent of 'because that's what it says on this piece of paper'). Plato also saw change as a delusion. According to Bruno Snell, Greek science generally lacked a concept of motion: in their enquiries their objective was 'to trace only the constant, static relations ... In the field of optics the Greeks did not pass beyond a geometry of light rays; and their scientific mechanics did not develop beyond statics.'¹¹ This is a profound insight that goes to the core of Platonism, and thence of Western philosophy, for centuries.

Aristotle thought that at the instant when movement starts, the object was neither at rest nor in motion – which is an odd response coming from the person who formulated the law of the excluded middle. It presumably indicates that he was stumped. An alternative response might be that no such instant exists, and that if it did, it would make change impossible. It seems to me that it is more reasonable to accept the existence of change and deny the existence of an instant, which is a theoretical invention, than to accept the existence of an instant and be forced to deny the existence of change, which is a matter of direct knowledge from experience.

'What Zeno shows', as philosopher George Melhuish puts it, 'is that *continuity cannot be composed of discrete elements* even if there is an infinity of them.'¹² It has to be inhabited whole; it cannot be composed from without. Flow is an irreducible, not an emergent, element in the universe.

A further paradox of Zeno's also concerns motion and is more outrageous still, but the same set of considerations apply.

- *The Arrow*. When the arrow occupies a place just its own size, it is at rest. At every moment during its flight, the arrow occupies a place just its own size. Thus at every moment of its flight, the arrow is at rest, and it never moves.

As Bergson writes:

A passage is a movement and a halt is an immobility. The halt interrupts the movement: the passage is one with the movement

itself. When I see the moving body pass any point, I conceive, no doubt that it *might* stop there; and even when it does not stop there, I incline to consider its passage as an arrest, though infinitely short ... but it is only my imagination which stops there ... as every point of space necessarily appears to me fixed, I find it extremely difficult not to attribute to the moving body itself the immobility of the point with which, for a moment, I make it coincide; it seems to me, then, when I reconstitute the total movement, that the moving body has stayed an infinitely short time at every point of its trajectory. But we must not confound the data of the senses, which perceives the movement [RH], with the artifice of the mind [LH], which recomposes it ... You substitute the path for the journey, and because the journey is subtended by the path you think that the two coincide. But how should a *progress* coincide with a *thing*, a movement with an immobility? ¹³

There are a number of hemispheric elements in all three of these paradoxes. First, retrospection is required because we are dealing with a left hemisphere *post factum representation*. It is true that, in the case of the arrow, retrospection does not seem to apply, but only because it is hidden in what is still an exercise in *post hoc* representation of a flight: the path, not the journey. Second, slicing of motion or time produces *stasis*, a characteristic of the left hemisphere's represented world. Third, the left hemisphere believes it can put anything together from *parts*. By contrast, the right hemisphere is dealing with what is *present* and actually experienced; it inhabits *movement* in time and space each of which has depth; and it sees that the *whole* is not the same as the sum of the parts.

On Zeno's paradox of Achilles and the tortoise, Bergson points out that nobody seems to have thought of asking Achilles how he did it. If asked he would have said, 'I don't have to take an infinite number of steps – I am past the tortoise in three strides'. And if anyone were to think of asking me, I'd say I don't have to take an infinite number of steps to get out of the room, nor does the arrow in flight get to be stationary at any point: except retrospectively, in the left hemisphere of the reader.

Note that time and space are always considered together in Zeno's paradoxes. This might be because, as Einstein believed, they were inseparable; but it is more probably because we attempt to understand time

by representing it spatially. That, according to Bergson, is where we make the fundamental error.

Related to this is a paradox promulgated by the Cambridge metaphysician JME McTaggart in 1908.

- *McTaggart's Paradox*. There are two main ways of thinking of time, claimed McTaggart: 'past, present and future' versus 'earlier or later'. The first is time as we experience it, in which the now of presence is constantly changing, and turning what was the future into the past. In other words, my 70th birthday lies now in the future and will one day lie in the past. He called this the 'A-series'. The second is time viewed from such a standpoint that there is no change: what was earlier (or later) will always remain so, however much time moves on. Nothing that can happen now will ever alter the fact that my birth was, is, and always shall be, earlier than my death. He called this the 'B-series'.

He deduced from this that time cannot exist, because (i) in the B-series there is no change, which is essential to time; and (ii) the A-series is self-contradictory, since it can never be true that anything that is in the past can also be in the present and in the future. If you were to object that this is to ignore the difference time makes, McTaggart would respond that that is to invite in the very thing he is engaged in deconstructing and has already shown to be incoherent – unless there is a second A- & B-series to ground the first, in which case the same arguments apply to them, and so a third pair of series will be required ... and so ad infinitum.

Once again the left hemisphere, in whose realm many philosophers seem to do most – or all – of their work, has represented time from a standpoint outside the flow and convinced itself that time does not exist. Just as Zeno demonstrated that, if you spatialise time, you are forever rooted to the spot, Achilles can never beat the tortoise, and an arrow can never fly, so McTaggart was stuck in 1908. Zeno was probably engaged in an amusing *reductio ad absurdum*; but McTaggart was in earnest.

Similar, but different, problems of division occur in a number of other paradoxes belonging to the class of the Sorites Paradox (Greek, *sorites*, a heap). Here, too, we find precision and stasis (LH) pitted against imprecision and evolution (RH).

- *The Sorites Paradox*. One grain of sand is not a heap. At no point does adding a grain of sand make the difference between being a heap and not being a heap. Yet after adding many grains there is a heap.

This has the same structure as a number of other paradoxes, for example that of Baldness (a bald man has no hair; adding a single hair at no point makes the difference between being bald and not being bald; yet after many hairs are added, he is no longer bald); and of Amphibius (a tadpole is filmed at 24 frames a second as it turns into a frog over three weeks; the first frame shows a tadpole, the last shows a frog; there must be a point in the series where a frame showing a tadpole is followed by a frame showing a frog, though only a fraction of a second separates them).

Again one sees a number of familiar hemispheric issues. First, words like ‘heap’ and ‘baldness’ are imprecise, and in this context, so is ‘frog’: they do not have sharp boundaries. To the left hemisphere this is just an example of not having thought clearly enough. Second, and related, there is no room conceded for partial assent (‘it’s getting to be something like what we could call, at a stretch, a heap’; or ‘thinning on top’, ‘balding’, ‘bald as a coot’): the left hemisphere prefers either/or answers. Third, the process of becoming a heap, or a frog, or ceasing to be bald, is turned into a series of sharply delineated individual, in themselves *static*, events – a series of *states*. Fourth, a heap cannot be recognised by enumerating its parts, but only as a whole. All four demonstrate left hemisphere predilections at work.

Fascinatingly, there exist philosophers who argue that, since the principle of bivalence is true (a proposition must be either true or false), there must be a single grain of sand which does make the difference – it’s just that we haven’t found it.¹⁴ I wonder if they also hold that there must be two consecutive frames, microseconds apart, one of which shows a tadpole and the next a frog? Many paradoxes hinge on a (psychologically perfectly understandable, but in my view philosophically mistaken) hungering for certainty.

Strangely enough, some game theory paradoxes arise from breaking down a decision that must be taken globally into what are, locally, logical steps, but which nonetheless lead inexorably to an illogical conclusion. This is a perfect example of what happens when the constrained vision of the emissary replaces the global vision of the Master. A paradox known as the

Dollar Cost Auction involves a series of individually irrefutably logical steps leading inevitably, by logic, to an illogical conclusion. The problem here is local focus and seriality, two cardinal features of the left hemisphere approach.

- *The Dollar Cost Auction.* A dollar is put up for auction, and goes to whoever bids the highest, in increments of 5 cents, however low that bid may be. But, according to the rules of this auction, the under-bidder pays the full amount of his bid and gets nothing in return. What happens is that once embarked on, it is impossible to exit a bidding war in which both parties lose.

The smart strategy would be for one party to bid 5 cents, and the other not to bid at all – and then agree to divvy up the gains fairly. But if co-operation is not allowed, what happens is that each tries by every means to avoid being the under-bidder, so that even winning and making a small loss (by bidding, eg, \$1.05) is eventually better than being the under-bidder, who would have spent a dollar or more for nothing at all. The logic here is symmetrical for either party, and so the game is bound to continue until everyone (except the auctioneer) is worse off than they were: in fact the bidding war will not cease until one party is bankrupt.

This has elements in common with the Prisoner's Dilemma, in which, once again, in the absence of co-operation, each party ends up worse off.¹⁵ There might be a message here that co-operation leads to logically superior results at the global level, even if competition gives the appearance of doing so at the local level. We saw this in the case of biological evolution. And once again, the right hemisphere is better able to see both the *overview*, and the worth of *co-operation* compared with simple competition.

Notice also how infinity has a habit of cropping up in the left hemisphere's version of the world: in reaching the door of the room, in the few strides that Achilles takes in real life to overtake the tortoise, in the regress of 'times' implied by McTaggart. Infinity doesn't actually come into it in real life in any of these cases. It is often entailed by the attempt to reconstruct a flow from slices, and then turn the resulting chain into a continuum. One of Minkowski's schizophrenic patients commented

balefully of his attempt to count endless sequences: ‘that leads toward infinity’.¹⁶

This is true of Lewis Carroll’s paradox of entailment.¹⁷

- *Carroll’s Paradox of Entailment*. Let us make the assertion: (X and Y) entails Z. One person might accept that X and Y are the case, but not accept that their combination entails Z; another might accept that *if* X and Y were the case, that *would* entail Z, but hold nonetheless that X and Y are not in fact the case. So it seems there are two separate propositions being made here, and the overall assertion thus becomes: (X, Y and (if X and Y, then Z)) entails Z. As you can see, this is the start of an infinite regress ...

There are two problems here.

The first is that a self-reference is involved. The assertion about what X and Y entail is on a different level from the assertion of X and Y themselves. So asserting the facts of the case – ‘it is raining’ and ‘rain makes you wet’ – is on one level; asserting that if these are the case they imply that ‘you are wet’ is not a statement of fact, but a matter of logic implicit in the syntax of the sentence. It is a meta-proposition, which should not be included in the very propositions to which it refers and on which it operates. I will come to paradoxes of self-reference shortly.

Carroll’s logical case shares an important structure with the Third Man Paradox, owed to Plato and discussed in its ‘Third Man’ form by Aristotle. Plato was honest enough to confess that it looked like an argument against the existence of Forms (themselves characteristic of left hemisphere thinking).

- *The Third Man Paradox*. According to Plato, Fred and Harry are alike, as ‘men’, because they each share the qualities of the Form of a Man, which must itself have all the qualities that Fred and Harry have. Thus, there are three elements that are alike: Fred, Harry and the Form of a Man. But how to explain their likeness? For this, there must be a further Form – call it the Superform of Man – which explains the likeness of each of the three to each of the others. So now we have four items: Fred, Harry, the Form of

Man, and the Superform of Man ... and you see where this is going.

This seems to me a consequence of creating an abstraction, and reifying it; thus ‘thingifying’ a mode of being, which is not a noun or a thing, and setting it on the same level as the supposed ‘things’ to which it itself refers.

So, first, there is a problem of self-reference. The second problem follows from believing the world to be made of wholly discrete elements, not overlapping patterns or flows. In trying to form connexions between discrete elements, the new connexions themselves need to be connected by a further overarching connexion, and so on, a point made in different forms by Bergson and James about the irreducibility of flows to chains. If A and B are wholly distinct, I have to yoke together A and B by means of a joining element C. The result is that where there was once just one pair of ends to join (the opposed ends of A and B), there are now two pairs, the opposed ends of A and C and the opposed ends of C and B:

As this process is repeated, in the attempt to unify the pieces of a chain, instead of the gaps being eliminated, they multiply without end. I hardly need to point out the hemispheric significance of this since it has been constantly emphasised in earlier chapters. This was formalised as a paradox by FH Bradley.

- *Bradley's Paradox of Relations.* If A and B are two terms that are connected, they are necessarily connected by some relation C. Equally for C to act as a connection, it must in at least some respect differ from each of A and B. Yet C can only relate A and B if there is some connection between A and C and between B and C;

so there must be new relations D and E to explain these connections ... and so ad infinitum.

It demonstrates beautifully that continuity can be disrupted, but cannot be created without some sort of leap. Continuity, like extension in space or time, cannot be put together, only taken apart.

Here I wish to quote James, because the passage is so much more revealing than anything else on this subject:

Suppose ... many distinct beings *a*, *b*, *c*, etc, to exist independently of each other: *can a in that case ever act on b*? What is it to act? Is it not to exert an influence? Does the influence detach itself from *a* and find *b*? If so, it is a third fact, and the problem is not how *a* acts, but how its 'influence' acts on *b*. By another influence perhaps? And how in the end does the chain of influences find *b* rather than *c* unless *b* is somehow prefigured in them already? And when they have found *b*, how do they make *b* respond, if *b* has nothing in common with them? Why don't they go right through *b*? The change in *b* is a *response*, due to *b*'s capacity for taking account of *a*'s influence, and that again seems to prove that *b*'s nature is somehow fitted to *a*'s nature in advance. *A* and *b*, in short, are not really as distinct as we at first supposed them, not separated by a void.¹⁸

The necessary preadaptation to *b* on the part of *a* – that what we take to be parts are already situated in a coherent whole – is an idea with which the reader will be familiar. For there to be a connexion between two entities there must be both a degree of difference *and* a degree of similarity.

These paradoxes should be distinguished from a quite different problem which arises through the business of representation, and then reifying our representations – both left hemisphere tendencies. We encountered it in the case of McTaggart's Paradox. He removes the force or movement from time, in representing it as a series extended in space (his series B); this means he needs to motivate the series (get it moving) by importing a second-order time (his series A), which might impart the essential quality of change, somewhere beyond or beneath it. And that then requires a third-

order time for the same reasons ... and so on. Similarly, there is a Paradox of Place, which was promulgated by Zeno.

- *The Paradox of Place*. Everything that exists has its place; place exists; therefore place too must have a place, and that place have its place, and so ad infinitum.

Here what seems to be happening is that the left hemisphere, dealing with representations rather than experience, finds itself in a hall of mirrors, in which a representation is represented by a further representation, which is represented by a further representation, and so on. Hardly surprisingly this paradox is bound up with the left hemisphere's version of language, whereby words are taken for the *things* they represent: a tool of representation.

Take the example of a paradox promulgated by Quine.

- *The Morning Star Paradox*. Both the Morning Star and the Evening Star are the planet Venus. But one has properties that the other doesn't have (such as appearing in the morning or the evening). Are they the same or different?

For our purposes it draws attention to two hemispheric traps: believing that naming a thing in two different ways might make two different things, and a reluctance to see that the same entity can appear at different times in a different phenomenological guise without losing its identity. This reluctance has something in common with Capgras syndrome, which as we have seen, is caused by a right hemisphere deficit: my wife in the morning is different from my wife in the evening because time has elapsed and she looks subtly different. Things, according to the left hemisphere – which invented them – don't change, because, remember, to the left hemisphere change doesn't exist. So when something does appear in two different lights, it implies, to this way of thinking, two distinct things.

Another kind of paradox also seems to hinge on the left hemisphere's tendency to see a name as a thing. An example is Kripke's Pierre, named after Saul Kripke who first promulgated it.

- *Kripke's Pierre*. Pierre, a Frenchman who has never been to England, has heard that '*Londres est jolie*'; so it could be said that he believes London to be pretty. Later he finds himself in a district of a foreign city, whose language he learns from those around him, and finds it is not pretty. He gathers the city's name is London, but makes no connection with the *Londres* of which he heard so much. As a result, he seems to believe that London is both pretty and not pretty.

From one perspective, until he is told that *Londres* and London are the same place, he does not have contradictory beliefs. Once told, he is free to reconcile them in any way he wishes – by, for example, telling himself that his experience of one area of London was not typical of London as a whole, or that London has changed since he first heard about it, or that he has better taste than his parents and friends, or that it is a curate's egg, or in a host of other ways. I would suggest that from a hemispheric perspective, though they operate in different ways, this and the Morning Star Paradox suggest the left hemisphere's difficulty in adequately distinguishing language from experience.

Then there is:

- *The Paradox of Negation*. To state that, eg, 'unicorns don't exist' is to imply the existence of something called a unicorn at the same time as denying its existence.

Once again, while one interpretation of the grammar is that I am affirming and then denying the existence of something, anyone familiar with how we use language will surely know that not everything we think corresponds to reality, and so neither does our language. By naming something, I do not bring it into being. We have words for ideas and images that we may know do not exist – or which we believe exist, though they don't. Once again an exaggerated notion of language as *constituting* reality, the natural position of the left hemisphere, seems to be part of the problem. According to Parmenides, you can speak only about what is: what is not cannot be thought of and what cannot be thought of cannot be. All three statements are false, it seems to me. As with almost everything that

Parmenides says, one is brought up sharply against the falsity of the left hemisphere.

Parmenides' position casts light on why Greek mathematics was never able to use 'zero', a concept they lacked and which was later derived by the seventh-century Indian mathematician, Brahmagupta. He recognised the significance of zero as an entity in its own right, thereby expanding the possibilities of mathematical calculation. Zero, he saw, was the result of combining any number with its negative counterpart: not just an absence, then, but the positive presence of x with $-x$. By doing so he made possible the development of modern mathematics.

Here let us consider a paradox promulgated by GE Moore.

- *Moore's Paradox*. Take a statement of the form ' x [where x is any statement, eg, 'this table is almost entirely empty space'], but I do not believe x '. The paradox here is that such statements appear absurd but are not necessarily untrue or contradictory.

There are a number of ways in which such sentences are not necessarily untrue or contradictory. All are illuminated, in my view, by a hemispheric analysis.

First, to the right hemisphere, it is taken for granted that what we say can only ever approximate a part of what we think or feel: to the left, which does the speaking, there is a greater temptation to imagine that words are the whole reality. Second, to the right hemisphere statements of belief are less purely cognitive and may take into account different levels of thought, feeling and experience. Third, to the right hemisphere, which is more in touch with our unconscious selves, it is easy to see how the same person may embody different levels of belief at any one moment in time. Similarly, it is also (eg, Capgras phenomenon, again) harder for the left hemisphere to see that multiple facets of the same person may exist together, and/or may change over time, without that person's personhood being at stake. In the words of Walt Whitman: 'Do I contradict myself? / Very well then I contradict myself, / (I am large, I contain multitudes.)'¹⁹ And fourth, there is the usual hemispheric difference in assent to *degrees* of truth – *partial* beliefs – ambivalence. Not to mention simply the left hemisphere's relative bafflement because of its poorer understanding of the complexities of human nature.

This relates to another paradox:

- *The Paradox of Self-deception*. How can one deceive oneself about something one knows to be false?

The correct response to that is: ‘very easily’, and I do not need to repeat the points made above. Denial – self-deception – is, as we have seen, a characteristic of the left hemisphere, so the supposed impossibility of self-deception may be in itself a form of left hemisphere denial – a denial of denial. But more than that, we are multiply stranded, and multiply layered, beings. The Paradox of Self-deception founders on believing that we are single and wholly conscious. To quote Montaigne: ‘within ourselves we are somehow double creatures, with the result that what we believe we do not believe, what we condemn we cannot rid ourselves of.’²⁰ So we may say: ‘I know I’m dying, but I can’t believe it’; ‘I am fearful of ghosts, but I don’t believe in them’; ‘I believe I’m fated, yet I know fate cannot be a reality’. My favourite is the remark reportedly made by Niels Bohr:

A friend was visiting in the home of Nobel Prize winner Niels Bohr, the famous atom scientist. As they were talking, the friend kept glancing at a horseshoe hanging over the door. Finally, unable to contain his curiosity any longer, he demanded: ‘Niels, it can’t possibly be that you, a brilliant scientist, believe that foolish horseshoe superstition?!’ ‘Of course not’, replied the scientist. ‘But I understand it’s lucky whether you believe in it or not.’²¹

Also related is

- *The Paradox of the Preface.*²² A writer may say, in the preface to his work, that ‘there will inevitably be errors’ in what he writes, but presumably believes that everything he writes is correct, otherwise he wouldn’t have written it.

Not for the first time, it is hard for a non-professional philosopher to believe that this counts as a paradox, but to the extent that it does, it must do so because of three criteria of interhemispheric difference: the *telescoping of time* by the left hemisphere, so that the present (the moment of the assertion) and future (when the envisaged mistakes will become apparent) are ‘flattened’; the conflating of a *general* truth with *particular* truths; and the loss of *gradation*, so that truths are now absolute.

It is evident that many paradoxes involve self-reference. We have seen several already. The most famous of these is the saying of Epimenides the Cretan, that ‘all Cretans are liars’: false if true, and true if false.

The most obvious response to such a paradox is that few statements apply inflexibly to every case at every moment in time. The right hemisphere doesn’t conflate the particular remark, which has a context, with an absolute, context-free proposition. In the real world, no-one reflecting that all Cretans are liars imagines an audience to understand that every single statement ever made by any Cretan was and is a lie. This is clearly an impossibility for a single functioning human being, let alone for a people that have been continuously civilised for nearly 5,000 years. Only someone who was autistic, or had some other form of right hemisphere deficit, could be expected to believe the remark in this absolute sense. On this I feel like Wittgenstein:

... it is very queer in a way that this should have puzzled anyone – much more extraordinary than you might think: that this should be the thing to worry human beings. Because the thing works like this: if a man says ‘I am lying’ we say that it follows that he is not lying, from which it follows that he is lying and so on. Well, so what? You can go on like that until you are black in the face. Why not? It doesn’t matter.²³

More interesting is to consider the *shape* engendered by the remark. If one sees this as a circle – if one flattens the plane of the argument – it makes no sense. But the meaning here is rich and has many levels. In three-dimensional, rather than two-dimensional, space, it is not *circular*, but has the structure of a *spiral*, in which the returning loop avoids re-entrance.

Let me be more explicit. One way of understanding the remark – which comes from a poem or song, and was probably humorous in intent – requires, as we have agreed, abandoning an inhuman, po-faced literalism, and understanding what goes on in another's mind (not a strength of the left hemisphere). After all, Epimenides was a man, not a computer. Epimenides, I suggest, knows that you know that this remark creates an absurdity, if he is to include himself as a liar. And so he seems to be exempting himself, making himself better than his fellow Cretans. In doing so he is also acknowledging that you know that that is what he is doing, and the very act of doing so risks exhibiting a lack of self-knowledge (boastful ignorance), which he is also mocking in himself. But by the act of mocking himself, he exhibits that he has self-knowledge at a still higher level. The humour comes from the 'I know you know I know' complexities involved (the phrase – more fully, 'I know *that* you know *that* I know *that* ...' – implies embedded levels of meaning, a more explicit playing out of levels, not just elements on the same level). By means of this, he draws attention to the sort of claims one cannot make about oneself – such as 'I am wise' or 'I am humble' – without self-defeat. And in doing so he leaves open the possibility that he may be wise and humble, while laughing at it and himself, at the same time, and suggesting he is probably neither. Leaving it to you to redress the balance. There! All of that so economically implicit, and understood by the right hemisphere; while according to the left hemisphere the statement simply 'does not compute'.

You could think of the two approaches here like this: the literal one is two-dimensional and therefore issues in a circle, while the nuanced one is three-dimensional, the circle becoming a spiral. The left hemisphere world is hermetic, so one 'hits one's head on the ceiling', so to speak, and can go no higher. But, according to the right hemisphere, to which all frames of reference are open, there is always another level to which one can go to ask a question that *transcends the frame of reference*. This difference of spatial depth, even if the space is a cognitive one, differentiates the two hemispheres.

One way of seeing the Liar Paradox is that two cognitive-linguistic planes are involved. The state of affairs described by the sentence has to be on a different level from the sentence itself (in this it is like Carroll's Paradox of Entailment). At one level language is being used to refer to a state of affairs outside language; at the second level, another statement is being made, from a higher level, about the statement itself, as a piece of language. In the first situation language is commenting or referring elsewhere, as it usually does; in the second situation, language is referred to from inside itself. These distinct levels are flattened, as though a spiral was squashed to a circle.

Yet another way of seeing it is that two temporal planes are involved. Thinking temporally, the sentence refers to a time before the pronouncement is complete – up until this speech event takes place. Then there is a second temporal context. The paradox results when the two distinct times are conflated.

Take another paradox of self-reference.

- *The Paradox of Euathlus*. Protagoras taught his impoverished student Euathlus the law on the basis that Euathlus would repay his teacher as soon as he won his first case. Euathlus decided not to pursue a career in law, and so did not repay Protagoras. Tired of waiting for his money Protagoras sued him for it. He reasoned that if Euathlus lost his case before the court, he would have to pay; and if Euathlus won his case, he would be bound to pay according to the terms of their agreement. However, Euathlus reasoned with equal force that if the court found in his favour he would not have to pay, and if it didn't he would still not be obliged to repay Protagoras, since he would not yet have won a case.

Here again the problem is self-reference, but it could be seen to resolve if one is careful to distinguish two different temporal contexts. At the moment the court makes a decision, both men are bound to abide by it. Suppose that the court favours Euathlus: Protagoras has lost his money. But only for now: if he then sues Euathlus a second time, he is almost certain to win, since Euathlus has clearly already won his first suit.

There are a number of self-referential paradoxes, most of which resolve if one is clear that distinct levels of language are conflated. To make a

statement A about a situation, and to make a statement B about the language in which statement A was made, are two different kinds of thing. However, some paradoxes are deliberately set up in such a way that language must refer to itself. An example is Grelling's Paradox.

- *Grelling's Paradox*. Developed by the early twentieth-century German logician and philosopher, Kurt Grelling, it involves referring to words that describe themselves, such as *short*, and *polysyllabic*, as autological, by virtue of the fact that *short* is a short word and *polysyllabic* is a polysyllabic word. Those which don't, such as *long*, and *monosyllabic*, are called heterological. Is the word heterological heterological? If yes, it isn't; if no, it is.

From a hemispheric point of view, language becomes itself an aspect of reality in the left hemisphere: 'what it says on this piece of paper' becomes as real as (indeed, more real than) the world of experience. The left hemisphere lives in what I have characterised as a hall of mirrors, in which it doesn't so much know the world by direct experience as know its own knowledge of its own knowledge of its own knowledge ... so that its thought becomes untethered from reality and highly self-referential.

Much of Magritte's work plays with levels of reference and the relationship between presence and representation. In *La Belle Captive*, the frame on the easel contains something that looks like a representation of the seascape in front of the viewer, so placed as to overlap with it exactly (see Plate 15). Is it, or is the frame merely empty, the seascape continuously present? The fact that the living fire surreally breaking from the tuba on the beach creates a glow on the area within the frame suggests a third possibility: that it is a blank piece of glass – something we need to see *through*. And in a painting such as his 1949 version of *Le Domaine d'Arnheim* (he repeatedly approached this visual conundrum from different metaphysical angles), the glass in the window is not blank but holds an exact painted representation of the scene beyond the window, revealed in the shards that have fallen on the floor.

The most famous modern paradox of self-reference is Russell's barber.

- *Russell's Paradox of the Barber.* In a certain village there is a barber whose rule it is to shave all those, and only those, who do not shave themselves. According to this rule, if the barber shaves himself, he must not shave himself; but if he does not shave himself, he must.

Notice that this works only if there are rules, that is to say *inflexible* rules. This is the left hemisphere mindset, and that is fine. What is worrying is that it is the world in which, guided by machine thinking, we are all increasingly expected to live.

Self-reference is sometimes endlessly generative and sometimes leads to a dead end. This is a case that is impossible: the barber cannot exist (if he is to abide rigidly by the rule). In this it is like the statement 'this statement is false': the statement cannot meaningfully be made. Garbage in garbage out. Yet the paradox has important implications to do with completeness. While it is fatal to the aspiration for a complete, closed system, it is not to an open one. In other words, the paradox demonstrates that following the consistent procedures of logic will always fall short of completeness, and any enclosed, self-referring system the left hemisphere comes up with, if taken strictly on its *own* terms, self-explodes: there is always a member of the system that cannot be accommodated by the system. There is always a way out of the hall of mirrors.

Let us turn to some paradoxes involving specifically the relationship of wholeness and parts. The best known of these is the so-called Ship of Theseus Paradox.

- *The Ship of Theseus Paradox.* According to Plutarch, 'the ship wherein Theseus and the youth of Athens returned had thirty oars, and was preserved by the Athenians down even to the time of Demetrius Phalereus, for they took away the old planks as they decayed, putting in new and stronger timber in their place, insomuch that this ship became a standing example among the philosophers, for the logical question of things that grow; one side holding that the ship remained the same, and the other contending that it was not the same.'²⁴

The ‘logical question of things that grow’ (*auxanomenos logos*), or Growing Paradox, refers to the argument that, since the cells (and for that matter, the constituents of cells) in all living things are constantly being lost and replaced, no organism is the same from year to year, or indeed even from moment to moment. Thought of as Novalis’s moulded rivers, or living streams, we could be seen either as the same, or not the same, like the Ship of Theseus: but in view of the way in which living things only remain the same through change (see Chapter 12), we would not normally deny continuity on this basis. In the case of the ship, to the right hemisphere, which sees the whole, the *Gestalt* has not changed, and the ship is still the Ship of Theseus; that a thing changes as it evolves is taken for granted. To the left hemisphere, which puts the ship together from its parts, it is not; when the parts change, it becomes something else. Those who find it difficult to see what the right hemisphere sees, such as people with schizophrenia and some kinds of autism, tend to doubt that they are the same person from moment to moment. This comes together with time-slicing, since both an inability to see that the whole is not the sum of the parts and the belief that flow can be sliced are aspects of the left hemisphere mindset.

Philosophers with such casts of mind run into the same problem. Descartes displays an essentially schizoid personality. He was an example of both extreme left hemisphere credulity (animals are merely machines and feel no pain, despite their cries when dissected) and left hemisphere scepticism (I have no continuity of existence; other people may be simply automata). ‘It does not follow from the fact that I existed a little while ago’, he wrote in his *Meditations on First Philosophy*,

that I must exist now, unless there is some cause which as it were creates me afresh at this moment ... it is quite clear to anyone who attentively considers the nature of time that the same power and action are needed to preserve anything at each individual moment of its duration as would be required to create that thing anew if it were not yet in existence ...²⁵

and he continues in the ‘Objections and Replies’:

there is no relation of dependence between the present time and the immediately preceding time ... the individual moments can be separated from those immediately preceding and succeeding them, which implies that the thing which endures may cease to be at any given moment.²⁶

So he argued in the seventeenth century.²⁷ And Derek Parfit argued a still more extreme position, in relation to the non-continuity of the person, in recent years.²⁸ In contrast to which I would urge the words of Bergson: 'I believe that our whole physical existence is something just like this single sentence, continued since the first awakening of consciousness, interspersed with commas, but never broken by full stops.'²⁹

A more intriguing version of the paradox can be entertained. Suppose someone kept all the rejected timbers as they were discarded piecemeal, and reconstructed them into a ship: which would now be the Ship of Theseus? If they each have a claim, are there now two Ships of Theseus, or just one, the issue of precisely *which* being undecided? Does the fact that in one case changes have been made only incrementally, without the *Gestalt* being lost at any point, make a difference? Suppose, then, that that ship is loaned to a museum, and is taken apart, and the pieces numbered and then reconstructed on arrival – is its claim for priority over the ship reconstructed from the old timber weakened? Why would the one that is reconstructed from new timber be *more* authentic than the one that is reconstructed from the original timber? And if the claim of the repaired ship is weakened by being taken apart, is there a moral argument against sending it on loan?

In such puzzles, where the whole is not living, but put together from parts, the left hemisphere and right hemisphere point of view seem equally to have something to be said for them. However, in the case of the ship reconstructed from the old parts, the situation is different: the one preserved in the harbour, in which new parts have been substituted, has *Gestalt* only: the one made from the salvaged parts has *Gestalt* plus parts, so that, on the face of it, it has more of a claim to be the original. But against that is the consideration of the difference between something that has gradually changed against something that had to be built up from scratch. We want to make a distinction there: for example, we would prefer the serially repaired

ship, even when it no longer contained any original pieces, to a replica made from scratch from new wood. Why? Presumably because we treat such a treasured object as having a history and fate shared with living things – caught up in the life of those whose narrative it shared; and to that extent we liken it to an organism. And in the case of organisms – those ‘things’ to which the Growing Paradox applies – it seems to me clear that the right hemisphere point of view is the more reasonable: I am still I (though changing, as every living being is), and the substitution of cells does nothing to invalidate the fact. It is the *Gestalt* that trumps all here, not the ‘parts’ out of which it is made. To reverse that in the case of living things is tantamount to rendering them inanimate.

Yet, as we now know, even non-living things, such as rocks, are pure *Gestalt*, since the constituent ‘parts’ are, at the atomic and subatomic level, in perpetual flux. *Everything* flows, and *at the same* time the flow keeps forming temporary *Gestalten* within the flow. There are distinguishable entities within a resonant whole. All this the right hemisphere is better equipped to understand. And here there is an intimation that the boundaries between the living and the inanimate are not as watertight as they are often assumed to be.

Let me conclude by touching on the two most problematic categories of paradox, those that involve time travel and/or future knowledge, and those that directly concern infinity.

Typical paradoxes of the first kind go like this.

- *Paradox of Prediction*. If you had certain knowledge of the future, you could take action in the present to alter events in such a way as to invalidate that knowledge.
- *Flint’s Paradox*. If you had both certain knowledge of the future and could travel into it, you could take action in the future to alter events in such a way as to invalidate that knowledge.
- *Grandfather Paradox*. If you could travel back in time you could kill your own grandfather when he was a child, so that you could not exist to travel back in time – so your grandfather would live, and you could be born to travel back in time and kill your own grandfather when he was a child ... and so ad infinitum.

These and similar paradoxes merely demonstrate the impossibility of certain future knowledge or time travel. I suggest that the problem arises because time, which is present to the right hemisphere, is re-presented as a sequence of events to the left hemisphere. Once it is laid out on paper, to know the future we need only look further along the line to the right, and to travel back in time we would need only to move our gaze to the left.

Thus spatialising time leads to paradoxes by encouraging retrospection, from some future imagined standpoint, on what can only be understood from the standpoint of the present (as in, for example, Zeno's paradoxes) or projection forwards to some future imagined standpoint of what can only be understood from the standpoint of the present.

An intriguing paradox involving prediction is Newcomb's Paradox.

- *Newcomb's Paradox.* Two boxes are on a table. Some (virtually) omniscient entity, Omega, has put \$1,000 in one box (A) and either nothing or \$1,000,000 in the second (B). It has done so on the basis that if it predicts you will choose just box B, the box contains \$1,000,000; if it predicts you will take both, it has put nothing in it. It has an astonishingly good track record of being right. Rationally speaking, should you take both boxes or just box B – bearing in mind that by now nothing can alter what is in the boxes, so that on the face of it you cannot possibly lose by taking both?

Mathematicians and philosophers divide pretty evenly into 'one-boxers' and 'two-boxers'. That is perhaps because there is no way of evaluating a situation that cannot exist. Accepting the omniscient being is like accepting that the porcupine is a monkey: any conclusion drawn from such a premise is invalid. I suppose it could be argued that there might come a time when a computer was so good at assessing your personality that it knew whether you were almost certain to be a one-boxer or a two-boxer. In that case the 'paradox' would simply become a matter of assessing, on the basis of everything else you know about the world, the weight to attach to the improbable claim – the being's track record might be a scam, or wrongly reported, or the result of a lucky streak, all of which are frequent causes of error in life, whereas no claim of infallibility has ever yet been validated. The left hemisphere takes one box, since it believes 'what is written on this piece of paper'; the right hemisphere takes two, if on taking a look at the

claim, it figures the claim is unlikely to hold – ‘the porcupine is not a monkey’.

Incidentally, in the case where Omega is a very efficient computer that can tell with astonishing accuracy whether you are a one-boxer or a two-boxer, you could game the situation by recognising that you are a classic one-boxer and deciding on this occasion to take two. To get round that Omega would have to know not just your boxing tendencies, but your cheating ones as well.

However, I suspect that the reason that there are as many one-boxers as two-boxers is not so much that people divide neatly into one of two groups, but that they are of two minds – sometimes favouring one-boxing and sometimes two. That would apply to me, at any rate. That we are inconsistent seems to have been forgotten, as in Moore’s Paradox.

And so to problems of infinity. The mathematician JF Thomson described the following paradox:

- *Thomson’s Lamp*.³⁰ If a lamp could be switched on and off an infinite number of times, each act of switching taking half the length of time of the previous one – the first lasting a minute, the second half a minute, the third a quarter of a minute (‘Zeno fashion’) – at the end of the two minutes that it would take to complete the series, would the lamp be off or on?

It could not be off, because every act of switching off is followed by one of switching on: and it could not be on, because every act of switching on is followed by one of switching off. There is no solution to this, except to declare the task not just practically but intrinsically impossible. This is an answer that is more tolerable to the right hemisphere than the left, because it involves accepting that some things can never be decided, and that some things can never be accomplished. As Margaret Cuonzo says, speaking of Kant’s antinomies: ‘although both antinomies are the result of trying to go beyond the limits of our reason, it is nevertheless inevitable that reason’ – for which, here read the left hemisphere – ‘will attempt to overreach its limits.’³¹

There are limits to our reasoning when applied to the stuff of reality, and this includes, but is not confined to, dealing with infinity. There is an

incompleteness intrinsic to mathematics when applied to the real world, where there are only irregularly curved surfaces and planes, not ideal rectilinear ones. A curved line has fundamental properties distinct from a straight one. Just as there is no way you can get to extension in space or duration in time by the amassing of infinitesimal points or slices, there is no way you can get to a curve using straight lines: you can approximate it with evermore tangents but never actually achieve a curve. A polygon with as many sides as you like never actually becomes a circle, though it approaches it asymptotically. A mechanised doll may be as lifelike as you can make it, but it will never actually live. The process in each case, the process that *doesn't* work, involves putting things together. In every case what can only be called a 'leap' has to be made from one realm into another, to bring it to life.

It's not just calculus (which is a rectilinear method of assessing non-rectilinear spaces that has to quit at some point), it's true of any curve, including a circle or sphere, since π is an irrational number, that is to say one that never resolves but goes on for ever. I am reminded again of Einstein's saying, 'as far as the laws of mathematics refer to reality, they are not certain; and as far as they are certain, they do not refer to reality.'

A 'leap' becomes necessary, I believe, not because of some disjunction in reality, but because of an incompatibility between the 'truths' that our two hemispheres hold. Bergson himself puts his finger on it when he contrasts the roundness of intuition with the rectilinear nature of logic. He says of the logician: 'Having in fact left the curve of his thought, to follow straight along a tangent, he has become exterior to himself. He returns to himself when he gets back to intuition.'

The profound fifteenth-century philosopher, mathematician, theologian, scientist and general polymath Nicholas of Cusa (often referred to as Cusanus), thought that truth is not a thing like other things, or put together from other things: it is irreducible. We can't arrive at more than an approximation to it, using what he called the intellect (effectively the analytic left hemisphere), much as a straight-sided figure cannot ever quite achieve a circle.

Leibniz, who invented integral calculus to deal with the problem of areas under a curve by endless approximation, said that we cannot step across the gap from finite, measurable spaces to the whole infinite space – to get across would require a leap. 'How slippery', he warned, 'are our

thoughts on infinity’.³² In order for asymptotes to meet, in order to move from the finite to the infinite, a leap is called for. And as he put it, ‘we cannot leap over’ by the unaided intellect.³³

This corresponds to Galileo’s explanation that the infinite cannot be reached by a successive progression of steps, but only ‘at a stroke’.³⁴ Galileo’s key perception was that the supposed endpoint of the sequence cannot be just *a special element of the sequence* itself, and similarly that an infinite number is not a special case of the finite numbers. David Hilbert was to say of infinity:

Instead of the old principle *natura non facit saltus* [nature does not make jumps], we might even assert the opposite, viz, ‘nature makes jumps’.³⁵

This leap is makeable by imagination but not by analytic reason. Infinity cannot be reached by continually adding another number to the series, or prolonging length or time indefinitely. An idea that is difficult for many people to grasp is that a line prolonged to a length of billions of billions of light years is no nearer infinity at the end of the process than when it was a thousandth of a millimetre long. To understand infinity we have to make a leap: you can’t get there by continuous movement from here.

I would suggest that the leap is from the incremental, computational (Newtonian), left hemisphere-compliant universe to an intuitive, non-incremental, non-computational (Planckian), right hemisphere-adapted universe. Discoveries in mathematics and physics often require a leap of the imagination, the so-called ‘aha’ moment of insight, which as we have seen is accompanied by activations in the right amygdala and right superior temporal sulcus.

Cantorian proofs can be constructed to show that two lines of any length – for example, an infinitely long line and one that was one millionth of an inch long – would both have the same number of points and that a line a millionth of an inch long has the same number of points as there are in the entire universe.³⁶ Nor is an infinity going to contain everything, just because it is infinite: the series of all whole numbers is clearly infinite, but so is the series of even numbers, which doesn’t contain the (infinite)

number of odd numbers that are in the series of whole numbers. Yet the series are the same size (a one-to-one correspondence between the elements of each can be demonstrated).

What this suggests is that we must not imagine infinity to be a noun and a quantity (left hemisphere fashion), and therefore a finished entity, but a process of a certain kind and therefore adverbial (right hemisphere fashion). Oddly enough, this is *not* to treat infinity differently from other mathematical symbols: all such symbols can be regarded as shorthand for processes, just as they can be regarded as things. For example, $\frac{3}{4}$ – three quarters of, let us say, a cake – seems thing-like; but it refers explicitly to the *process* of dividing three by four. Irrational numbers (called irrational because they can never be finally resolved), such as π or $\sqrt{2}$, reveal the point starkly, because the alternative to the thing-like symbol, which is a useful shorthand for mental manipulations, is to carry on a process of division that can never terminate. The process is never-ending, but the thing is finished. We therefore need the symbol for practical purposes. As Hermann Weyl remarked: ‘*mathematics is the science of the infinite*, its goal the symbolic comprehension of the infinite with human, that is, finite means.’³⁷

Quantum mechanics poses paradoxes of its own. Surprisingly, Quine accepted that the ‘problem’ with quantum mechanics might rather be a problem with conventional Western logic. ‘Revision’, he wrote

even of the logical law of the excluded middle has been proposed as a means of simplifying quantum mechanics; and what difference is there in principle between such a shift and the shift whereby Kepler superseded Ptolemy, or Einstein Newton, or Darwin Aristotle?³⁸

Take the Einstein-Podolsky-Rosen paradox. This asserts that it follows from the principles of quantum mechanics, which provide the most complete and most accurate account of the nature of physical reality, that two quantities may instantaneously (with no temporal delay) influence each other, and without there being any contact between them. Einstein was so appalled by this that he spent the rest of his life trying to show that quantum mechanics was incomplete – without success. Because, if it is true, the cosmos is not composed of entities that exist in their own right, influencing

one another, but of patterns that are reflected in reciprocal movements of what only come to look like entities when they are observed by us. Louis de Broglie, the founder of quantum wave mechanics, wrote:

In physics, as in every other branch of knowledge, the problem of continuity and discontinuity has existed at all times: for in this science, as elsewhere, the human mind has always manifested two tendencies at once antagonistic and complementary. On the one hand, there is the tendency which tries to reduce the complexity of phenomena to the existence of simple elements indivisible, and capable of being counted; a tendency whose analysis of reality seeks to reduce it to a dust-cloud of individuals. On the other hand, there is a tendency based on our intuitive notion of time and space, which observes the universal interaction of things and regards every attempt to disengage definite individual entities from the flux of natural phenomena as artificial ...³⁹

De Broglie, like Bergson, could have had no knowledge of hemisphere difference, but seems to have intuited it perfectly from his knowledge of physics: how physical reality appears to the mind.

It is time to make the leap from reason to intuition.

INTUITION, IMAGINATION &
TRUTH

INTUITION'S CLAIMS ON TRUTH

The heart's unrest is not to be stilled by logic.

—*Friedrich Waismann*¹

If you have intuitions at all, they come from a deeper level of your nature than the loquacious level which rationalism inhabits.

—*William James*²

There is in us something wiser than our head.

—*Arthur Schopenhauer*³

IN THIS PART II OF THE BOOK WE ARE CONCERNED WITH THE PATHS BY which we may approach the truth. Contemporary culture favours science and (very much in theory) reason as the ultimately valid approaches, and is deeply sceptical about intuition and imagination – the former because it is regarded as primitive, quirky and unreliable, and the latter because it supposedly just ‘makes things up’. I suggest that this is profoundly mistaken. In Chapter 19, I will explore how intuition, in the form of producing insights, acts with imagination to establish our sense of the world and of what we can truly say about it. But first, I want to look at the role of intuition in everyday life – in how we manage the business of living.

Such intuition has had a bit of a bad press lately. Academic psychologists and philosophers are inordinately fond of thinking up experimental situations in which we are deceived by what our ‘intuitions’ tell us. These are a sort of cognitive counterpart to intriguing optical illusions: in this figure, for example, we (think we) *know* square A and B can’t possibly be the same shade and colour – and yet, I promise you, they are.

Fig. 34. Chequerboard illusion (created by EH Adelson)

Don’t believe me? Take a look at Plates 16 [a] and [b].

However, I never heard of anyone saying, after being shown a good optical illusion, ‘that does it: from now on I’m going to live my life with my eyes closed’ – whereas a lot of people seem to have come to the conclusion that intuitions are the sort of thing bright people should avoid having.

Our intuitive capabilities are often misrepresented: they are, as I shall show, less erroneous than one might assume.⁴ For instance, impressions of other people are often surprisingly accurate even when formed on the basis of very brief exposures, through ‘very subtle, almost imperceptible, nonverbal cues ... so subtle that they are neither encoded nor decoded at an intentional, conscious level of awareness.’⁵ We are fairly accurate at identifying emotions from non-verbal behaviour that we have glimpsed for only about 300 milliseconds.⁶ Often, as we will see, people make better judgments by intuition than they do by conscious deliberation.⁷ Gut

feelings are surprisingly reliable;⁸ and inferences drawn from gut feelings are not blind, but amenable to modification in the light of subsequent experience or reasoning.⁹

What is more, intuition is not just a sort of quick, but ‘rough and ready’, *faute de mieux* way of arriving at a decision that would be far better done explicitly over a longer period. It is not only faster but much more capable of dealing with more, and more complex, information. ‘For all nontrivial problems’, writes the jurist Christoph Engel,

calculating the best response is cognitively way too taxing. This, however, is true only for the consciously controlled handling of information. The automatic system handles huge amounts of information in almost no time. Only the end result is propelled back to consciousness as an intuition. Consequently, in appropriate contexts, institutions should in principle see to it that decision-makers trust their intuitions.¹⁰

Which is not to say that there are not times when the admixture of conscious deliberation pays off – why else would we have developed the capacity to add it? Just that its relationship with intuition has often, and increasingly, been wrongly conceived and projected. And we have come to mistrust, indeed allowed ourselves to become anxious about, a capacity for understanding the world which we should be celebrating.

LET'S GO TO THE RACES

A couple of years ago, a French race horse trainer, Franck Mourier, got in touch with me after reading *The Master and his Emissary*. He was 47, and had a master's degree in physiology. From childhood he had had a passion for horses. As a young man at university he researched and established a complex mathematical model for selecting the best thoroughbreds based on the correlation of around a hundred parameters. He saw himself as very methodical and analytical. All his life he had been involved in buying, selling and training racehorses.

Now retired, he lived in England, and made a living by going to the races every day and acting as a tipster. His job was to watch the runners for a few minutes before a race, and estimate each horse's chances of winning. He then produced what is called a tissue (a sheet of paper showing the 'form' of the horses competing in a race). He had done more than 1,200 such tissues over the previous year and kept records and an analysis of all the data. 'Surprisingly', he commented, 'my percentage has been consistently better and more accurate than the market consensus.' But he and his colleagues soon began to notice 'some strange facts that should upset any rational mind'.

Two minutes before the race started, he would communicate the tissue to his partners, who then exploited any difference between his opinion and the market. When he rang to give his predictions, there would typically be a conversation such as this:

Franck (reading from the tissue): Love Dreams ... 50% ... But I don't believe he can win!

Team: Ok, but why did you put 50% chance to win, then?

Franck: I really don't know!

Team: What should we do then?

Franck: I don't know!

Team: The race begins in one minute, the market on Love Dreams is 20%. What do you want us to do?!

Franck: I don't know, change Love Dreams to 20% ...

‘As you can imagine’, he told me, ‘Love Dreams then wins,’

and the team are upset because they weren’t able to take advantage of my tissue. Such examples went on and on, until the day when the team said, ‘Don’t call us anymore. Just text us your tissue and don’t comment on it!’ This produced better results, of course, but the fact that I have to keep my mouth shut really torments me.

He had also noticed that the more pressure he felt under to come up with a good tissue, the worse he would do:

Previous life experience taught me that the more preparation you make, the more commitment you have and the more you focus on a goal, the more likely you are to achieve it. Strangely, after analysis of the 1,200 tissues, it appears that the opposite is true. And if I write one bad tissue (one in which I do worse than the market), I am three times more likely than chance to write another bad one in the following race ... I can’t help it; again, the harder I try, the worse the results.

He found that he was getting a little better at dealing with it, but was still handicapped by emotions such as self-blame, fear of losing, and aversion to risk that got in the way of ‘simply trusting what I see’.

A year passed, and he wrote to say that he had made ‘significant progress’. He had come to realise that the problem was that he just could not believe his own success:

How can I pretend to know that horse A is going to run a mile one-tenth of a second faster than horse B, just by looking at them for a couple of minutes before they run? It doesn’t make any sense to me, but somehow it consistently works! The margins between winners and losers are always terribly slim. So how is it that my predictions can be so accurate – consistently better than everyone else? It creates a terrible discomfort; I am still never truly secure and confident about a tissue I’ve just written.

On his suggestion, his wife Capucine ('Capy') also wrote to me to explain what she had observed. At first, in his new role as tipster, Franck had seemed rather odd, insecure and ill at ease. She could not understand why it was that, although he could see how good his predictions were, he refused to go ahead and process any tissues. In an effort to help understand, Franck had started reading various books, including *The Master and his Emissary*. A few days after starting reading it, he apparently told her: 'Iain is talking about exactly what I am experiencing, in the way he describes the brain hemispheres'. He was amazed by the sense of having discovered 'a new part of the brain he was not aware of using before, and as a scientist and left-brain user he did not want to accept it or believe it ... and yet he was really moved by what he had learnt.'

Capy, also a horse trainer, with a background in law and economics, then also read the book and felt a similar realisation. As a result of this, at least as she and her husband put it to me, a number of things changed. 'We needed to find ways to help Franck shut off the constant presence of "the left brain". He started being more open, talking about his emotions (something new!); he became more sensitive to the things around him, and became more creative.' As a result, Franck's role in the family had changed, and, along with it, their relationship, in a whole range of ways – much (as they both confirmed) for the better.

He had been 'tipping' races between five and 10 times a day for more than two years, and now had a rich database of more than 3,000 tissues, which were analysed by the team so as to monitor his performance. He was proud to report that his success meant that he made considerably more than a comfortable living.

I asked him to describe what he actually did. He explained that a meeting consists in a succession of six to eight races with 30 minutes between each of them. Before each race, the horses are led into the paddock, and walk for a few minutes around it; five minutes before the race, the horses will gallop to the start. He, like the rest of the crowd, would observe them, with or without binoculars. He would then write a tissue, which would usually take about 20 seconds, in which he would accord each horse a percentage chance of winning, and then send a text to his team. 'I do not fully understand why I am writing these percentages in front of each horse', he told me, 'and, surprisingly, the less I understand it the better it is. I never go to the races with too much previous knowledge and information.'

When I have a tissue already in my head before I see the horses it usually results in disaster.'

Conscious that experts can rarely articulate how they are able to do what they do, I nonetheless asked if there was anything he was aware of looking out for. He replied:

I am really at a loss to explain what I am seeing, and have generally no real clue how I come to a percentage. It is definitely a combination of a lot of factors – but if I had to name a few, they might be: Does the horse look happy or worried to be on the racetrack? What is the quality of the relationship between the horse and the person that leads him to the race? Does the horse appear healthy and fit? Are jockey and horse a good match? Does the horse trust his jockey and listen to him? Can the jockey understand the horse and communicate with him properly? But again these are just some impressions. It is not consistent and certainly not straightforward ... Anyway, after the race we can immediately see the accuracy of my predictions. Then the process starts again in the next race.

It seemed to me that Franck could have a second career as a psychiatrist, were he in need of one, which he clearly wasn't. But how, I wondered, had he come to realise that these intangible feelings about relationships were more important than any measurable facts about the horse? He couldn't say.

By close scrutiny of his record, he and his wife had worked out that there were a number of factors that made a significant difference to his performance. For example, his 13 year-old son loved to come to the races with him, and Franck really enjoyed his company. He was supportive, very knowledgeable about horses, and understood what his father's job entailed. But a comparative analysis of the 100 tissues written when with his son and 100 from the same period when he was on his own showed that with his son he averaged £0 per tissue, while without him he averaged £1,000 pounds per tissue. 'This asymmetry could not be explained by chance alone', Franck remarked, 'so the team asked him kindly to stay at home'.

He needed also to dissociate himself from 'anything material or financial' during the mornings before the race, and to remain ignorant of the

amounts at stake, or it would ruin his form: ‘The best results are achieved when I see it as just a game with no pressure ... as if I am going to the races just to enjoy the horses and write the percentages I feel.’

He also reported that he used to wake up very early most of his adult life and could get away with very little sleep. Now he and his wife had noticed that he needed a long sleep, ‘and I do even better if I have a little nap in the car, right before the races start’.¹¹ The significance of this will be touched on later.

This story, it seems to me, describes perfectly the plight of an intuitively gifted person in a society resolutely hostile to intuition. So bad have things become that we have difficulty accepting indisputable facts because our theory contradicts them. Unusually, this was a situation in which intuitions could be tested against incontrovertible and immediate evidence, time and time over – and yet so deep is the mistrust with which we have been indoctrinated, that Franck initially became miserable, withdrawn and immobilised by anxiety, rather than accept the reality of his gifts. Of course, the idea that my book made much of a difference I put down to the generosity of the account I was given; it may, though, have provided Franck with an insight into a scientific basis for accepting his own intuitive faculties.

‘While the American army was being menaced by hidden improvised explosive devices’, writes Peter Struck, in a recent scholarly examination of the history of divination in the ancient world,

certain soldiers appeared to their comrades to have preternatural abilities to sense the presence of these bombs. The army, in a deeply pragmatic spirit, poured money into studies of such people, trying to see whether there was anything to the anecdotes. Cognitive scientists determined, in a finding not at all surprising to those familiar with the discipline, that some soldiers indeed had more accurate predispositions to sense trouble than others. When the soldiers were asked to describe how they knew something was out of order, they called it a hunch, or a gut feeling ... It is, of course, more than just uncanny that two millennia ago the single arena in which the seer’s gifts were most consistently valued was also the battle field. According to the Greek military handbook by the 1st-century CE tactician Onasander, a general should be temperate, self-

restrained, vigilant, and hardened to labour – and he should also be a skilled reader of entrails, so he can be personally involved in the readings his diviners are giving him ...¹²

Perhaps there was an intuitive metaphorical connexion between experiencing gut feelings and inspecting entrails. But there is more to it than that.

Speaking of ‘gut feelings’ may, like our references to the heart in matters of deep emotion, be more literally correct than we have become accustomed to think. Both feelings of anger and a ‘broken heart’ can trigger a heart attack.¹³ A meta-analysis shows that it is the right hemisphere that predominates in receiving and interpreting information from the heart.¹⁴

The gut and the psyche have close connexions. Anxiety, depression, and other disorders have characteristic expressions in gut behaviour – and the associations work both ways: diseases of the gut affect mind and mood. As well as containing 95% of the body’s serotonin, which also acts, as is well known, as a neurotransmitter in the brain, and is thought to be involved in affect regulation, the gut has some 200–600 million neurones, rather more than there are in the brain of a dog.¹⁵ And most of the neural traffic is from the *gut to the brain*, not the other way round. You can take it that they are not all just there to control peristalsis: ‘The system is way too complicated to have evolved only to make sure things move out of your colon.’¹⁶

Struck gives an account of the famous Pythia, the High Priestess of the Temple of Apollo at Delphi, to whom ‘people that had run up against the limits of their own knowledge brought their remaining questions’. He emphasises not just her female sex, which the Greeks associated with ‘body over mind’, but her ‘legendary illiteracy’; and that for them what was felt to be divine in nature was deeply rooted in the corporeal, in what we share with animals, bypassing the everyday realm of the explicit on the way.¹⁷ When she spoke, her utterances were famously oblique, and came in the form of poetry. ‘When that realm which lay above us chose to speak’, he writes, ‘the messages mostly came in and through the one that lay below us. It does not simply stand to reason that the phenomenon would be organized this way.’

In most non-Western cultures, people describe a faculty or faculties, corresponding to intuition or a sixth sense, whereby they can discern

matters absolutely not present to consciousness. We should be careful to attend to this and not dismiss it as ‘superstition’.

INSTINCTS

Many of the patterns that organise and make sense of the dance of life in animals – and importantly in humans – come from somewhere, we have little or no idea where or how: instincts. Instincts are usually taken to mean deeply embedded drives that do not have to be learnt, are not pursued as conscious aims, and find their fulfilment directly in their expression. Examples might be the instinct to eat when hungry, and probably the choice of *what* to eat (eagles don't waste time on strawberries); to drink when thirsty; for a predator, to hunt; for prey, to look out for predators (hens that have been brought up from chicks in barns immediately show fear reactions when exposed to predators they have never before encountered); for a bird to fly (birds brought up without the opportunity to observe or be guided by adult birds nonetheless fly when released from confinement);¹⁸ in migrant animals, to migrate; to make a home – a den or a nest of some kind; to seek a mate, to take part in ritual displays and to procreate; to protect one's mate, one's young and one's territory. There are others that are more highly evolved: to form relationships;¹⁹ in apes and humans, and probably other taxa as well, to imitate members of one's own species (human infants will in some cases copy an adult's facial gesture as little as 45 minutes following birth);²⁰ to utter in order to communicate (in many species), to sing or call (in birds), arguably to develop language (in humans); both to compete with, and, in mammals at least, to empathise, and co-operate with, other creatures.

But there are many, many others. William James indeed held that humans, rather than having somehow 'cast off' their instinctual nature, having fewer instincts than animals, had many more: 'man possesses all the impulses that they have, and a great many more besides. In other words, there is no material antagonism between instinct and reason ... no other mammal, not even the monkey, shows so large an array.'²¹ If imitated patterns of behaviour become hardwired – and they do – and we are the imitative species, *par excellence* –and we are – this makes perfect sense. James's colleague CS Peirce, who thought that we were born not just with the basic biological inclinations, but 'certain tendencies to think truly about physics, on the one hand, and about psychics, on the other', wrote: 'if you

are going to think every poor chicken endowed with an innate tendency toward a positive truth, why should you think that to man alone this gift is denied?' ²²

As far as the chronology is concerned, instinctual drives are always 'on' in the background of our lives. At times they can be accentuated for obvious reasons, and at times they can be overridden, though James thought they could be overridden only by a contrary instinct, and that cognition in and of itself had no power to gainsay an instinct, having a role, rather, in leading one towards a position where a counter-instinct could be reinforced. Instincts can also wither, if the environment affords no opportunity for them to be established – or if systematically disattended to, as in our society today.

Here I should mention an interesting recent development. The idea of human instincts about physics and 'psychics' that Peirce alludes to, and that James suggests are so numerous, is a way of accounting for shared forms of thought and feeling, of apprehension of the world, of knowledge and understanding even, that appear to be in us without ever having to be learnt – something reminiscent of Jung's idea of the collective unconscious. We now have suggestive evidence of possible mechanisms of transmitting one generation's experience to the next. For example, it seems that trauma suffered by Holocaust survivors may have been passed on to their children.²³ A genetic study of 32 Jewish men and women who had been interned in a Nazi concentration camp, or witnessed or experienced torture, or who had had to hide during the Second World War, showed that they and their children exhibited epigenetic changes not found in children of Jewish families who were outside Europe during the War. The changes were in the region of a gene that is known to be involved in regulating stress; the children also had an increased likelihood of stress disorders.

This builds on research in animals, showing that induced fears in one generation may be inherited by the next. Mice were trained to fear the scent of cherry blossom by coupling it with a small electric shock, so that eventually the mice showed a fear reaction when exposed to the scent on its own. The offspring of these mice, despite never having encountered the smell of cherry blossom before, or having any reason to associate it with anything unpleasant, had the same fearful response to the smell on first exposure – and so did their own offspring. Epigenetic changes at the site of a gene responsible for detecting this scent were found.²⁴

The implications of this are important, and incidentally form an example of how scientific intuition can eventually win out against dogma. It used to be doctrine that acquired characteristics could not be transferred to the next generation: Lamarck, who was intuitively right, was held to be plain wrong. With the discovery of the importance of epigenetics that has changed. Perhaps Lamarck was not so wrong after all. Many beliefs that were once intuitions only have been found to have a basis in science, and I have no doubt that many more will in the future, as the horizons of science inevitably expand.

One of the great questions in this continually evolving universe is how it is that we come to express, without being taught, patterns of behaviour, patterns of thought, that we share with our ancestors, and why do we not have to wade through all the options laboriously in order to rediscover them. Enculturation is an obvious response, and one that is surely correct up to a point; but it doesn't by a long way cover all the observable phenomena, including the inheritance of tastes, physical gestures, mannerisms, predilections, of people to whom we are physically related but whom we have never met – and even possibly by transplant of an organ, such as the heart, though that is still controversial at this stage.²⁵ As a grandparent I have seen physical mannerisms, facial expressions, and tastes unmistakably expressed in my children and grandchildren that are identical to those in forebears they never knew.

Rupert Sheldrake's idea of morphic resonance seems to me a concept very well worth considering seriously, though in the current climate in science it is generally anathema.²⁶ According to Sheldrake, morphic resonance is

a process whereby self-organising systems inherit a memory from previous similar systems. In its most general formulation, morphic resonance means that the so-called laws of nature are more like habits ... Thus each individual inherits a collective memory from past members of the species, and also contributes to the collective memory, affecting other members of the species in the future.²⁷

The question, of course, is: how? It is often objected that this would be to endorse the existence of forms that can be detected only by their

consequences. As David Bohm rightly stressed (*à propos* another matter, though he was certainly not dismissive of morphic resonance):

There is no reason why an extra-physical general principle is necessarily to be avoided, since such principles could conceivably serve as useful working hypotheses. For the history of scientific research is full of examples in which it was very fruitful indeed to assume that certain objects or elements might be real, long before any procedures were known which would permit them to be observed directly.²⁸

In fact, being at least open to the hypothesis is necessary in order even *to make the observations* that could validate the hypothesis.

Epigenetic changes may be a special case of such morphogenetic fields in operation (after all, like all fields known to physics, they would have to interact with material mechanisms in some way). Recently, the frequency of oscillation of electromagnetic fields has been found to make the difference between carcinogenic and cancer-inhibiting effects on organisms, and this is not a one-off finding, but consistent with a large and rapidly growing body of evidence – the mechanism is, however, uncertain.²⁹ Yet a tumour can be seen as, in some practical sense, an independent organism with its own primitive morphogenetic field;³⁰ an ‘opportunistic, self-organizing, and adaptive complex dynamic biosystem.’³¹ Whether it realises itself or not seems to depend on the resonances within a field.

Instincts are, indeed, much more remarkable than we often assume. How do complex patterns of behaviour become present to offspring that may not have known their parents – for example, the complex mating routines of hummingbirds and birds of paradise, or the octopus’s building of a garden out of attractive shells? Not to mention a bird ‘simply’ flying, or building a nest of a certain kind in a certain way in a certain sort of place, or, in the case of a cuckoo, invariably *not* building a nest, but flying thousands of miles in order to commandeer some luckless other bird’s nest? Or a spider weaving its web? How is it that repeated patterns of behaviour create changes that allow such complex four-dimensional behavioural patterns to be transmitted from generation to generation? Where exactly are these patterns instantiated?

Are archetypes something similar to this? Jung suggested that instincts and archetypes were related as, respectively, motor and sensory phenomena with common ancestry: ‘instincts are typical modes of action’, while ‘archetypes are typical modes of apprehension’.³² An archetype is not like a stereotype. Unlike the stereotype, which is a *post factum* abstraction that is purely general in nature, the archetype exists *ante factum*, and is instantiated. It is the coming together of the absolutely unique with the absolutely universal – in fact this absolutely unique experience is felt as both absolutely unique and absolutely universal at the same time. Every time someone falls in love, the experience seems unique, as though it could never have happened before or ever happen again in the history of the world. And yet it is as ancient as humanity itself – or older – as the experiencer also acknowledges. It is both a typical human experience, and a completely unique one, of unmatched power and significance. And so it is, to one extent or another, with all archetypes. In fact their constantly repeated nature is part of their power: according to Jung, ‘endless repetition has engraved these experiences into our psychic constitution.’³³ When we encounter them afresh, it is the experience, not of cognition, but of recognition, or anamnesis. The finding of the universal in and through the unique, rather than by turning away from it, is a theme I will recur to.

Jung was influenced by both anthropology and the study of the evolution of animal behaviour patterns. From these arose his idea of the archetype as a structuring principle, which he found reflected in the history of both philosophy and mythology.³⁴ We can observe motor instincts more easily than we can observe the reality of the archetype within consciousness. Since we know, however, that perception and sensory function are tied to motor function, each depending for its coherence on the other, it seems probable that archetypes will exist as the imaginative counterparts to instinct. Jung argues that instinct and archetype ‘determine one another’,³⁵ and he suggests that the archetypal may be experienced as an affective state through an image, metaphor or myth.³⁶

Jung thought of archetypes as paths that our ancestors had traced, or rivers they had followed, and that every time an experience of this powerful nature was recovered it opened up an ancient riverbed:³⁷

Archetypes are like riverbeds which dry up when the water deserts them, but which it can find again at any time. An archetype is like an old watercourse along which the water of life has flowed for centuries, digging a deep channel for itself. The longer it has flowed in this channel the more likely it is that sooner or later the water will return to its old bed.³⁸

We are transmitters, as D.H. Lawrence said. It may be that much of our thinking and behaviour is relayed to, and through, us: not originated by us at all.

Instincts are not the same as intuitions, since they seem to be general and inherited, though forms of behaviour and thinking we might not generally call instinctual may be inherited too, as the findings of evolutionary psychology suggest, and so the difference cannot be absolute. Intuitions may have taken a long time in evolving, both through individual experience *and* through that of a whole historical culture. As anthropologist Merlin Donald puts it,

individual decisions are made in the brain. Human brains, however, are closely interconnected with, and embedded in, the distributed networks of culture from infancy ... Humans are collective thinkers, who rarely solve problems without input from the distributed cognitive systems of culture.³⁹

As far as the significance of the hemispheres goes, most of these drives are dependent on subcortical regions, some as deep as the brainstem, and certainly the limbic system. Such global drives cannot be ascribed to one hemisphere alone.

THE BALEFUL EFFECTS OF CONSCIOUSNESS

On the Isle of Man, off the west coast of Britain, there is an annual event called the TT races. This is a terrifying motorcycling event quite unlike normal circuit events, since it takes place on ordinary public highways, and has been described as the most dangerous sporting event in the world. By an act of the island's independent parliament, the Tynwald, the island's roads are closed to ordinary road users for two weeks. A medical consultant who looks after the well-being of the contestants wrote to me with some intriguing observations. He began by explaining the origin of his interest in the competitors:

Why TT racers, not circuit racing? There are significant differences: circuits are smooth, little high speed, many corners, and a grid start. Riders are focused on each other and corners are tactically vital, so position and braking are key. The TT, by contrast, is a time trial, so no grid start, riders go off individually and race their own time, so to speak. A map of the course suggests many corners, but the fast ones say there are only three, the rest are fast sweeps. Fast is the key here, as sustained speeds are now up to 200mph, which is nowhere sustained on any British circuit. Finally it is a normal island road, which is not smooth, not swept, and with drain covers, patch repairs, etc. It is nearly 40 miles long and climbs from sea level over the mountain; the weather is different around the course and the mountain can be fairly gusty. The key is great *smooth riding* – there is no late braking or diving under; and good TT racers don't generally do well on circuits. It is a specialised and dangerous game: there are no run off areas, just stone walls, which it is normal to brush the leathers against at speed.

So clearly there is little room for error: what those who are successful can tell us will be of considerable interest. What do they report?

An example: the speed past the grandstand is around 175mph, yet just past is a blind brow covering a fierce drop down Bray Hill,

which has a kink at the bottom. I suggested to a good racer that surely you have to be inch-perfect at the grandstand, as you do not have time to correct your line before the plunge down Bray Hill and the kink at the bottom. He replied that when you go past the grandstand you're thinking of the Quarterbridge. Now the Quarterbridge is a mile further down the track ... It begs the question as to exactly what the present moment means to these chaps.

Conscious will is a handicap. The doctor described two riders battling

the whole way with very close times. They started together and stayed together for the whole race until the last lap when [X] missed a gear coming out of Ramsey, saw his fellow disappear in the distance, and with only the climb up the mountain to go knew he had lost. Happy to come second, he 'backed off', as he said, but to his amazement caught the lad up fairly soon, and overtook and won. It is possible that, by abandoning the determination to win following the missed gear, he removed a small bit that was interfering with his actual capability ... A similar tale involves the truly great [Y] who, following a pitstop fumble, had lost too much time to win, so accepting second place as a given, backed off to run a risk-free last lap. He broke the lap record, a very difficult thing to do, requiring absolute perfection, and did not believe it when told, as he thought he was little more than touring home.

Further observations were:

- all anxiety goes when they start, almost like a switch; some say their body vanishes (ie, they are so in their body that they don't notice it as distinct from the self);
- they operate in a weird state where they say they are 'way ahead of the bike': pictures that show their eyes at difficult parts of the course would make you think they are quite unfocused, gazing at infinity;

- perception is quite markedly improved, which may be visual, but is also auditory and tactile, and ‘they are quite happy to include a sixth sense’; one rider describes entering a ‘horrendous fast descent to a tricky left hander and noticing a spectator stood back in a field light a cigarette, saw the puff of smoke blown by the wind, and smelt the tobacco inside his full face helmet’;
- they say they have all the time in the world, in fact time slow-down is almost universal, particularly in accidents, where they are able to think and act in slowed down time.

My correspondent had another fascinating observation. Racing engines get extremely hot and ‘operate very close to piston seizure’, so the temperature gauge is vital. One rider had fitted a new digital gauge: his performance deteriorated drastically and he only regained form after re-fitting the old analogue one. The digital gauge presented him with changing numbers, whereas the analogue presented a sweeping scale. Having to ‘read’ the digits, rather than see the position of the needle, interfered with his smooth racing. And the number would flicker and change, over a degree or two of no consequence, all the time: the sweep gauge supplied the trend without distraction. My correspondent wondered if some accidents were due to the left hemisphere taking hold.

The ideal state described is one in which attention must be far from the immediate point in space and time, instead inhabiting the whole feel or shape of the course as it unfolds; the passing of time and the presence of the body are not noticed – not because they have gone away, but precisely because they are so completely inhabited that they are no longer available for inspection, no longer ‘objects’ to which focussed attention could be drawn. They are no longer *in* the field, they *are* the field. All is *zuhanden*, nothing *vorhanden*. This enables ‘smooth-riding’: being in the flow. All anxiety, which narrows attention, all analytical thinking or interpretation, all distracting, obtrusive detail, must be banished. It is not unlike some aspects of both a trance-like meditative state and the mental state described by practitioners of Japanese martial arts.

Experiments with experienced handball players indicate that they make better decisions when they have less time.⁴⁰ Expert golfers (though *not* novices) do better when they have only three seconds to putt than when they can take all the time they want.⁴¹ Analytical decision-making seems to

interrupt the intuitive processes that serve experts well. This is not confined to non-cognitive tasks. Instructing individuals to verbalise their reasoning disrupts otherwise effective processes that are outwith the realm of language, leads to over-focus on elements of the superficial structure of the problem at the expense of the depth, and can lead to poor decisions.⁴² This is the phenomenon known as ‘verbal overshadowing of insight’.⁴³

As Peter Struck’s comments on the Delphian Pythia suggest, it seems that we make our best judgments about risk outside the petrifying stare of consciousness. Unconscious influences lead us to the right answer, and in their absence conscious strategies do not suffice – indeed, they can impede. We often revise better decisions taken more intuitively and replace them with worse decisions after thinking them through more explicitly.⁴⁴ Experiments have indicated that conscious deliberation (explicitly verbalising and analysing reasons when making decisions) can have a disruptive effect.⁴⁵ As a corollary, being prevented from deliberating is not always detrimental to, and can improve, decision-making.⁴⁶

In a famous and often repeated lab test called the Iowa Gambling Task, subjects are asked to turn over cards from four packs, two red and two blue. Depending on the card, they will either win or lose money, and their goal is to maximise winnings. Effectively the red cards are disastrous – you can win well, but you can also make heavy losses; and the best strategy is to stick to the blue cards which give you regular, modest winnings. Although it takes subjects usually about 80 cards to be able to articulate what is going on, they are able to verbalise a preference for the blue cards after about 50. However, in one study, the subjects were hitched up to a polygraph (a ‘lie-detector’), that measured how sweaty their palms were. What this revealed, astonishingly, was that after only 10 cards, long before the subjects were conscious that there was a difference, the polygraph registered that they were more anxious when their hands hovered over the red cards: and that already at this point, though again the subjects were not aware of it, they had *actually started to change their behaviour* to accommodate the new information. Long before the conscious mind reached its conclusions the body had perceived what was happening and was already responding to it.⁴⁷ It should not surprise us to learn that lack of awareness of emotions negatively affects intuitive decision-making.⁴⁸

When asked for their judgments about which decks rated good or bad, subjects often responded in a manner discrepant with the actual choices they made on the task. Unconsciously they were aware of what their articulate left hemisphere was not. It seems that, when information conflicts, we tend to favour implicit over explicit knowledge; until we are asked to reflect on the matter consciously, verbally – with the reverse outcome.⁴⁹

Not everyone's 'gut feelings' are helpful, however, and for some individuals they lead to consistently wrong choices. Whether this is because such people are trying too hard, and the conscious effort is getting in the way, is not known. But one possibility may be that those more alert to their own autonomic responses, such as their heart beat, are those who make the best players. When subjects were tested for their ability to monitor their own heart beat prior to the gambling task, it turned out that those who were better able to do so – literally to listen to what their heart was telling them – were better at the game.⁵⁰

This was interestingly reflected in a study carried out by Stuart Valins in the late 1970s. It had been previously reported that an increased heart rate was related to higher levels of accuracy in interpreting facial gestures,⁵¹ and that heart rate was one cue that some participants were aware of using to gauge appropriate responses when asked to respond to visual stimuli.⁵² A group of people were filmed while concentrating on a gambling task. When other subjects were asked to interpret, from the facial expressions on film, how much money someone had just won or lost, the subjects were separated into so-called 'intuitives' (those who responded almost immediately, but could not verbalise about their process) and 'intellectuals' (those who delayed responses until the latter half of each trial session, but *could* verbalise about their process). Each subject did the test four times, in two blocks of two. On one occasion in each block they were given reinforcement, in the form of monetary reward, if they got a right answer. On the other they were not. And then the order was varied, so that they did both conditions again, but in reverse order, in order to rule out an effect of precedence.

What the experimenters discovered was on the surface puzzling. Overall, there was no difference between the two groups in terms of efficiency. However, under reinforcement conditions, the level of accuracy for intellectuals was significantly higher than for intuitives: but under *non-*

reinforced conditions, intuitives performed significantly more accurately than intellectuals. In other words, for intuitives, the rate of accuracy actually declined significantly when they were given immediate reinforcement about correct responses.

The phenomenon of ‘choking’ refers to the well-attested fact that people often do worse on a task when the reward is higher – a familiar phenomenon in sport, but also in the workplace. Why would that be? One possibility in the Valins test is that the external reinforcement drew attention consciously to performance, made them self-conscious, and interfered with their sensitivity to the internal cues they were receiving from their body.⁵³ But there are others. A study of people playing a computer game in which they had to catch prey looked at the brain correlates. As expected those offered the higher rewards did worse. On the scans, there were changes in midbrain function (ie, at the level of the brainstem) between the two conditions, but the cortical areas which were more active in the low-reward than high-reward condition as the subjects approached their target were the right anterior cingulate and right medial prefrontal cortex.⁵⁴ If these were relatively ‘switched off’ by trying too hard for the higher rewards – remember the left hemisphere is acquisitive – that would explain why ‘intuitives’ were more handicapped than ‘intellectuals’ in the high-reward condition. Note that the conscious mind thinks it knows best, despite its lack of understanding.⁵⁵

We are often – in fact, usually – unaware of the patterns that govern our insights.⁵⁶ They operate only at the unconscious level and are often quite complex. Arthur Reber, a pioneer in the field of implicit, or unconscious, learning, showed that people can learn complicated patterns without any awareness of doing so. Simply from memorising a list of letter strings (derived from a ‘grammar’ of which they are completely ignorant), subjects can judge subsequent test strings as ‘grammatical’, or not ‘grammatical’, even though they have no conscious sense of why, eg:

'Grammatical' strings	'Non-grammatical' strings
VXJJ	VXTJJ
XXVT	XVTWJ
VJTVXJ	VJT TVTV
VJTVTV	VJTXXVJ
XXXXVX	XXXVTJJ

Moreover, knowing beforehand that the letter strings to be memorised have come from an underlying grammar *decreases* the subjects' performance, presumably because it alerts the left hemisphere to look for rules it is not going to be able to articulate.⁵⁷ Several studies have shown that the ability to learn at an implicit level is impaired by asking subjects to look actively for complex patterns, an effect that has been called the 'benefit of not trying'.⁵⁸ As one team put it, 'learning predictive relations between events depends on *attention*, not on awareness'. That sounds rather like the way that many skills are learnt: by a habit of receptive *attending*, that is more important than awareness – and might actually be inhibited by awareness; though in the earlier stages explicit rules can help up to a point.⁵⁹ This ability to detect a pattern in the absence of verbal awareness is *prima facie* likely to be mediated by the right hemisphere, a hypothesis that is confirmed by superiority of the left hand over the right when asked to respond in such circumstances.⁶⁰

It might seem obvious that you take things in better when you are focussed on them; and that you will make better decisions if you are thinking about the question that needs to be decided. But neither of these is necessarily the case: in fact often the opposite applies, as repeated psychological studies have suggested.

In one study subjects were asked to look at a series of abstract images. During half the task they were able to concentrate, but during the other half they were deliberately distracted. When they were later asked to identify images they had seen, they did better on the pictures they had viewed while distracted.⁶¹ When, in another study, subjects were asked to detect the odd one out in a field of symbols, responses were more accurate when time was severely limited (to less than half a second).⁶²

Furthermore, in a test of originality, subjects were asked to generate items in response to a cue. There were three conditions: in one, they had to respond immediately; in the second, after a few minutes' conscious thought; and in the third, after being distracted for a few minutes on another task. The most creative and original answers came from the group that had been distracted.⁶³

Using a geometric and spatial insight problem, it was found that providing participants with breaks improved their performance as compared to participants who did not receive a break. However, the length of incubation between problems did not matter. Thus, participants' performance on insight problems improved just as much with a short break (four minutes) as it did with a long break (12 minutes), suggesting that disruption of conscious deliberation was enough to improve performance, irrespective of the *length* of disruption.⁶⁴

In another study, this time of decision-making, subjects were asked to evaluate the best out of four models of car on the basis of 12 criteria.⁶⁵ One group were given time to ponder before coming to a decision; the other had to move on immediately to address another task after reading the information through, and then made a spontaneous decision later. The first, 'pondering', group chose the best car only a quarter of the time, whereas about 60% of the 'spontaneous' group made the right choice. Some other studies suggest that subjects make better decisions immediately after reading all the characteristics than after *either* a short period of conscious consideration *or* a short period of distraction, suggesting that it's more that their first thoughts are best than that there is a period of unconscious 'mulling'.⁶⁶ But overall it would seem that a (brief) period of 'mulling' does improve judgments.⁶⁷

Interestingly, the advantage conferred by distraction seems only to work when the participants are induced into an appropriately holistic way of thinking (they are asked to form a global impression of each alternative) not when they are encouraged to adopt a 'featural' one (in which they are asked to compare individual attributes of the alternatives).⁶⁸ For example, participants who are simultaneously engaged in a distracting task are able to differentiate good from poor shares on the basis of 75–150 numerical return values that were presented at a fast speed – but *only* when the participants were asked which shares 'feel better', rather than, for example, to report

which of the shares had the highest average, which encourages focal attention.⁶⁹

The ‘conscious’ and ‘unconscious’ are not wholly distinct realms. The whole discussion of ‘conscious’ and ‘unconscious’ processes is set up as though the two were different species of fish kept in separate tanks. As I have argued elsewhere, the boundaries of consciousness are fluid, and elements can come and go from conscious awareness from millisecond to millisecond, rather as objects ‘appear’ and ‘disappear’ when a spotlight moves around a stage. And the field of consciousness at any moment in time has no sharp edges, but a ‘fringe’ around it where it meets the unconscious. This area on the edge of awareness is far more fruitfully creative than the centre of the field of consciousness. The essential point is whether what we ‘see’ is paralysed by *focussed attention*, such as the left hemisphere applies, or freed up by *attention to the field as a whole*, as is the case in the right hemisphere. Arguing about consciousness versus unconsciousness misses the point. If we are able to bypass that dichotomy, there emerges a point on which both sides (proponents of conscious and unconscious ‘processing’) might be able to agree: closing down to narrow attention is what needs to be avoided, whether by depriving the serial-processing left hemisphere of time, or by distracting its Gorgon stare elsewhere.

While I am on this topic, I am often asked whether the unconscious mind can be identified with the right hemisphere. It is sometimes argued that the right hemisphere is less conscious than the left, and most neuropsychologists seem to assume that this is so: I understand what is meant.⁷⁰ To the extent that what we mean by unconscious is ‘outside the spotlight of attention’, the answer is a definite ‘yes’. But this doesn’t mean it has no awareness of the world, indeed quite the opposite. After a major left hemisphere stroke the subject has a greater awareness of the world than someone who has had an equivalent stroke in the right hemisphere – even, arguably, in some respects greater than normal.⁷¹ Any unconsciousness here is limited to a lack of *self-conscious* awareness.

The key point to remember is that what is capable of being retained in the centre of our field of awareness is very limited indeed, and when we use only what we see there to construct our view of reality we go wrong. Not just because of how little we can see there, but because even the little that we *can* see is necessarily distorted by the type of fixing, isolating,

abstracting, distancing, devitalising attention brought to bear on it. To this extent we rely heavily on the right hemisphere and what it knows – all of which, from the left hemisphere point of view, is classed as ‘unconscious’, since it knows very little about it.

It is this very large field open to the unconscious, by comparison to the conscious, that Malcolm Gladwell’s interesting account in his best-selling book *Blink* appears to me to miss. He supports the idea that intuitive expertise relies on reaching a conclusion on the basis of minimal information: but by identifying ‘thin-slicing’ – which he interprets as the sampling of very few elements in a picture – he gets hold of exactly the wrong point.⁷² What is distinctive about the unconscious mind is not how little, but precisely how much, it takes into account, very quickly. This was the point made earlier by jurist Engel of the Max Planck Institute. By contrast with the conscious mind, which cannot hold all the information at once, and therefore tends to focus only on a handful of salient details – sometimes simply the last details it heard – the unconscious mind appears capable of dealing with complex patterns that can’t easily be reduced. Gladwell’s substitute for this holistic perception is what he calls a ‘thin-slicing flurry’.⁷³ Of course, looked at from the perspective of the analytic left hemisphere, that’s what it must seem to be. Yet what is actually being represented is a brief but *continuous process*, not a small *series of slices*.

Part of the power of the unconscious mind is its capacity to deal with numerous different elements *simultaneously* – and, even more importantly, to see their interconnexions one with another. This form of parallel processing is central to pattern recognition because it is able, without obtruding into conscious awareness, to take note of complex simultaneous events, and the emergent patterns of connexion: a seamless process.

There is a tendency to think that because it is quick, it must rely on a simplifying dirty trick. Not so. Equating unconscious intelligence with the ability to reduce situations to a simple underlying pattern is at best incomplete.⁷⁴ In some types of situation it may be possible to reduce matters to simple underlying signatures, but these are unusual – those in which one or two pieces of information have a disproportionate role in the outcome. The conscious mind can maintain in an active state and process only four to seven pieces of information at the same time.⁷⁵ It is at its limit when recalling a phone number it has just heard. However, the unconscious mind does not have the same limitations. The intuitive embodied parallel

processing approach is essential: rather than being just a source of bias, it integrates across a huge range of values and judgment factors.⁷⁶ And experiments on implicit learning reveal that, as the underlying pattern gets more complicated, the unconscious mind tends to have the advantage – which does not seem to fit with what Gladwell would have predicted.⁷⁷

Gladwell makes good use of the intriguing case of the Getty *kouros*, but draws, it seems to me, the wrong conclusions. This concerns a purportedly archaic Greek sculpture of a naked young man (a *kouros*) that the Getty Museum acquired, believing on the basis of extensive documentation and a number of expert opinions that it was genuine. However, other experts, asked to examine it, found themselves extremely dubious, sometimes referring to incidental details (one refers to a detail of the fingernails), but generally appealing to a sense that it immediately – and it was in almost all cases an immediate reaction – looked wrong as a whole. One said that it felt too ‘fresh’. Another said that he felt physically sick in its presence. Eventually, after piece upon piece of paperwork attesting its ancient provenance proved to be a forgery, the case for its authenticity started to look thin.

It is notable that the famous art historian and connoisseur Bernard Berenson described his talent for validation of masterpieces as a sixth sense. ‘It is very largely a question of accumulated experience upon which your spirit sets unconsciously’, he said:

When I see a picture, in most cases, I recognize it at once as being or not being by the master it is ascribed to; the rest is merely a question of how to fish out the evidence that will make the conviction as plain to others as it is to me.

Berenson recalled that once, upon seeing a fake, he had felt an immediate discomfort in his stomach.⁷⁸ We are back to the guts. Here we have more than one expert talking about feeling physically sick or feeling an immediately unpleasant sensation in the stomach on seeing something that was intuitively wrong with a work of art.

In the Getty *kouros* case, from the perspective of the conscious mind, these judgments certainly appear to happen in a very thin ‘slice’ of time, so must depend on a thin ‘slice’ of information – right? Wrong:

these conscious reflections reveal little about what was going on in the art historians' unconscious minds. The expert who found himself staring at the statue's fingernails and the expert who judged it too fresh likely blended below awareness a large amount of physical or stylistic information to conclude the statue was a forgery. The inarticulateness of the judgments of most of the experts, on the one hand, and the credence they gave these inarticulate judgments, on the other, argues even more clearly for the complexity of the underlying patterns behind their conclusions.⁷⁹

There is a 'give and take' between the conscious and unconscious minds. We can consciously decide to hand over to the unconscious: thus it can carry on working while the conscious mind focusses on something else. We don't do this as often as we might. For a solution may only appear with time and unfocussed attention, allowing a broad survey of relevant material: 'mind wandering may ... allow otherwise opposing networks to work in cooperation.'⁸⁰ Note the suggestion that the unconscious mind is not disturbed, as the conscious mind is, by the coming together of (apparent) opposites.

Equally the decision to take more conscious control may arise, but that decision itself *arises from the unconscious*.⁸¹ All thought is ultimately intuitive in its provenance, in the sense that it is grounded in unconscious intelligence, which elects either to explore it consciously or not; much as our sight is macroscopic, and it is from that oversight of the world that we decide to take a close view of some detail through a magnifying glass – not the other way round. Most of what the unconscious mind knows, of course, never gets into the focus of awareness, but when it does so, it happens some while later: the unconscious shows signs of having solved a problem as much as eight seconds before the solution comes to consciousness.⁸² It is also of interest that both the heart and the brain appear to be able to anticipate an error in performance by musicians.⁸³

Clearly some decisions, detection tasks, and creative acts do require deliberation and cogitation, even focussed attention. It's just useful to be reminded of quite how much goes on *better* as long as it remains outside the spotlight of attention, since our immediate unexamined assumption, coming from the explicit articulate left hemisphere, is that we do everything better

when we are focussed on it and trying hard. In reality such occasions clearly do exist, but they are relatively rare. (I will consider a striking example later in this chapter.)

Before we leave this section, what about the time course here? The laying down of whatever it is we draw on when we speak of having gut feelings takes a while, and may go back a long way. But access to knowledge that is stored seems to take anywhere between milliseconds and several minutes, presumably depending on how much information needs to be retrieved from memory. We make judgments about a person's trustworthiness, competence, aggressiveness and likeability within the first tenth of a second, judgments which do not change significantly with added time.⁸⁴ This might go to show how accurate our first impressions are – or just how difficult it is to change them subsequently. But, either way, judgments on complex matters, that are hard to specify, are made almost instantaneously, and we generally feel no need to alter them.

EMBODIED COGNITION, PATTERN RECOGNITION AND THE EMERGENCE OF SKILL

Much of what we call intuition is the result of what John Kay calls ‘finely honed, well-developed skills’.⁸⁵ ‘Well-developed’ here means repeatedly exercised through practice, and it is on the grindstone of experience that our intuitions are honed. Even if they manifest as cognitive, they are embodied, in the sense that they are both informed by and inform the motion of our limbs, our breathing and pulse, the emotion of our heart and gut and mind, together with alert perception, and intelligent insight, all manifest in interaction with, rather than abstraction from, the world. Such intuitions are highly context-sensitive, responsible and responsive, not random or wilful; they are the fruit of disciplined attention to the world over time.

It is this kind of intuition, something that is grounded in praxis, not analysis, that is the decisive element in chess,⁸⁶ just as it is in calligraphy, or playing the cello.

Chess is often thought of as an analytic game, but it clearly is not: it is an expertise operating almost entirely at a non-conscious level. Deliberation does take place, but on a ready-made selection (typically not more than half a dozen) out of literally millions of possible future scenarios, and, contrary to what is often believed, does not necessarily look more than a few steps ahead. Professionals can play simultaneous games, sometimes against as many as 50 opponents, with only slightly less success than in games played under tournament conditions. In simultaneous play, the professional takes much less than a minute, often only a few seconds, for each move. There is no time for careful analysis, which, if systematic, would take thousands of hours. A chess expert is, rather, an expert at perception: it is skilled perception, not unaided memory, that enables the chess Grandmaster to memorise nearly perfectly a position that has been presented for a few seconds only, as detailed analysis of the eye movements of strong and weaker chess players, when confronted with a novel position, shows.⁸⁷

The difference in perception is that the expert already sees, not a mass of details that have to be organised by rules to make sense, but patterns that have meaning within the game. That their skill is a matter of pattern recognition, not just a photographic memory, is demonstrated by the fact

that though such experts are much better than normal subjects at remembering a board in a chess game after glimpsing it for a few seconds, this superiority to a great extent (though not entirely) disappears, if the task is to remember a random arrangement of pieces that has no meaning within the rules of chess.⁸⁸ It is worth watching the memory performance of chess Grandmaster Patrick Wolff, available on YouTube.⁸⁹ What is clear is that he is relying heavily on right hemisphere brain functioning: he talks of seeing coherent patterns that fit together in chunks right across the board. ‘You try to absorb everything quickly, but occasionally you overlook the details’, he says – but he had already demonstrated that he does not overlook any single piece *if it is important*, that is, if its presence or absence would in any way change the overall meaning of what is seen. Such a piece could not, in any case, ever be an isolated ‘detail’: it would be already bound into what he calls the ‘structure’. It is only the inessential that he forgets, with astonishing efficiency.

How good are we at knowing whether we have seen something before? The answer appears to be ‘very’. ‘A number of studies demonstrate that recognition memory is vast, easily etched on, and remarkably retentive despite short presentation times’, according to psychologists Gerd Gigerenzer and Dan Goldstein.⁹⁰ An experiment in 1967 by Roger Shepard had shown that immediately following a single exposure of 612 picture stimuli, for about six seconds each, subjects could select the correct picture in two-alternative recognition tests with a 98% success rate.⁹¹ Over the next few years, another psychologist, Lionel Standing, went further:

Standing increased the number of pictures (photographs and ‘striking’ photographs selected for their vividness) to 1,000 and limited the time of presentation to five seconds. Two days later, he tested recognition memory with pairs of pictures in which one had been presented previously and one was novel. Participants were able to point to the previously presented picture 885 times of 1,000 with normal pictures and 940 times of 1,000 with ‘striking’ pictures. Standing then outdid himself by a factor of 10. In perhaps the most extensive recognition memory test ever performed, he presented 10,000 normal pictures for five seconds each. Two days later participants correctly identified them in 8,300 of 10,000 pairs. When

more and more pictures were presented, the retention percentage declined slightly, but the absolute number of pictures recognized increased ...

This is despite the effects of fatigue: Standing himself reported that ‘in the case of 10,000 items, the cumulative effects of five days’ viewing ... are extremely gruelling and unpleasant’.⁹²

In his experiments Standing compared pictures and words, and considered that ‘the superiority of the pictorial mode in recognition and free recall learning tasks is well established ... recognition memory for pictures is almost limitless’. He was referring here to both accuracy and capacity. The average recognition time for words and images was less than a second when there were 10,000 objects. The unconscious memory can work on shapes, pictures and images, juggling many factors, in very short periods. Standing reckoned that, given a further second, the mind could search over 50,000 pictures in unconscious memory.

There are also things that can never be recalled because we weren’t aware of them at the time – yet we know them at some level. If ‘we’ don’t know that we know them, how can we be so sure? Well, we are much more than our conscious selves; it is variously estimated that around 99% of all that our brains take note of never needs to break into conscious experience. This, incidentally, partially explains the results of Libet’s well-known experiments (and the subsequent similar experiments of Soon and others)⁹³ – they are not a proof that in some spooky way our ‘brain’ makes decisions that ‘we’ don’t know about, still less that there is ‘no free will’. They merely require us to accept that we are more than our conscious minds, and that most of our decision-making goes on at a level below consciousness, something which, if it wasn’t already obvious, was made abundantly clear over a century ago by Sigmund Freud. Most of our knowing is ‘knowing without knowing why’, as psychologist Guy Claxton felicitously puts it.⁹⁴

When asked to find a fourth word that linked another three (such as HOME, SEA, BED) people are better than chance at discriminating a triad for which such a word exists from one which has no such word, even when they are not able to name the fourth word.⁹⁵

Sometimes this ‘knowing without knowing you know’ can manifest itself in some interesting ways. Fearful faces exposed for as little as 17-thousandths of a second, and then followed immediately with a neutral face

that ‘masks’ it, can nonetheless evoke a response in the amygdala, showing that an appropriate emotional reaction to the fearful face occurs, even though subjects are completely unaware that they have seen it.⁹⁶

In a condition known as blindsight, the primary visual cortex (also known as the striate cortex, or V1) has been destroyed or damaged in such a way that subjects are blind, in the normal sense of the word. Yet if asked to guess the presence and location of an object, they perform better than they could by chance. They can even ‘guess’ the colour and shape of an object or its orientation, and react spontaneously when something moves; and can catch something thrown at them, put out their hand and grasp, eg, a walking-stick by the handle, and recognise whose face they are looking at – yet they nonetheless insist that they see nothing.

A patient called TN, who was cortically blind, exhibited what is called affective blindsight. He was able to react spontaneously to facial expressions, with an appropriate emotional response accompanied by activity in the right amygdala, even though he denied that he had seen anything – and indeed, in the conventional understanding of the word ‘see’, he had not.⁹⁷ He was also able to walk down a corridor negotiating a range of awkward obstacles that had been placed in his path, some low to the ground, some higher – a bin, a tray, a tripod – and avoided every one of them. He had to squeeze up against the wall to get past a bin: when asked why he did it he said he ‘just felt like’ walking that way.⁹⁸

This phenomenon has been much debated by philosophers, who have used it both to support and to deny the existence of consciousness. But there is something very odd that is less often noted. Subjects with blindsight are both less surprised by their ability than we feel they ought to be, and at the same time, much less confident in their ability than we feel they ought to be – they carry on needing to be prompted to use it (as did Franck Mourier). Something like confabulation is evident. The conscious articulating mind, not knowing what is going on, prefers anything to accepting the truth of the matter – that we are getting along OK without its input. The situation is similar to that found in split-brain patients, when the right hemisphere is aware of something that the left hemisphere is not, and the left hemisphere, nothing abashed, constructs a story to make sense of what has just happened, without having a clue as to what actually did.

Aristotle distinguished three kinds of knowledge: *episteme*, *techne* and *phronesis*. They don’t have exact equivalents in English, but they can be

explained without too much difficulty. *Episteme* is abstract, context-independent, invariant and general. It is based on analytical reasoning. In our terms, it represents the left hemisphere in action. *Techne* is the skill of the craftsman: practical, embodied, flexible and dependent on context. *Phronesis* is a kind of pragmatic wisdom, which involves the appreciation of values, is more reflective, but is also flexible, tacit, intuitive and context-sensitive like *techne*, to which it is closer than it is to *episteme*. Both *phronesis* and *techne* show signs of being more right hemisphere-dependent. Aristotle also distinguished *nous* (intuition) and *sophia* (another kind of wisdom). These are each harder to put into modern English terms, but *nous* is something like the intellectual spirit that enables us to reason at all, while *sophia* (the root of our word ‘philosophy’, and usually translated as wisdom) interestingly covers a very wide range of experience, bringing together, more clearly than any other, what is conventionally seen as the ‘lowest’ level, embodied wisdom, with ‘highest’ level, inspired (or divine) wisdom. In ancient Greek thought, these were not sundered: Homer is, for example, able to speak of the *sophia* of a shipbuilder,⁹⁹ and Theocritus of the *sophia* of a tapestry-weaver.¹⁰⁰ At the same time, the word may also mean insight into the deepest nature of things by a poet or thinker. It is also often used interchangeably with *phronesis*, the wisdom of judgment that comes with experience.

Most importantly, Aristotle realised that different kinds of knowledge were appropriate to different contexts, so that the knowledge of an accountant was of a different kind to that of a physician, and each was different from that of a sculptor.

What sorts of knowledge are needed to develop expertise? And what role does intuition play? Those of you who have read Daniel Kahneman will likely have a somewhat jaundiced view of expertise. What Kahneman says should not be ignored: I will come to that in the next chapter. But meanwhile what *does* make an expert?

You need to start by consciously learning a very great deal, for years; but in the long run that will never make you an expert. There are far too many options to consider for you to cover them all in the time available – which is not to say that experts don’t think or deliberate. They very definitely do. But it is important to know how much, and when, to do so. Too much self-awareness, or self-awareness at the wrong moment, will not

help; indeed it will positively get in the way of good judgment or good practice. Judging that, too, is part of expertise.¹⁰¹

In this, expertise is like a Japanese martial art,

full of balancing acts that demand the application of rigorous technique and the surrendering of the self to its most intuitive state. In Kendo, rigour is acquired through strictly repetitive drills, and flexibility only becomes possible when the fencer is proficient enough to ban all thought of rigorous technique and respond intuitively.¹⁰²

Something similar applies to being an experienced physician. As a medical student starting out on the wards, I had learnt a colossal number of pieces of information – several a minute, on average, it certainly seemed – over the previous three years. At times it had felt like trying to drink from a fire hose. Yet for all that, I was completely at sea when it came to putting what I had learnt into practice. As part of my training, I was encouraged to introduce myself to patients and take their history. I particularly remember that, as a medical student, after almost two hours of listening to one poor middle-aged lady, I had no clue what was wrong with her. She wore wrist splints and, having tried to kill herself, was brought in in a wheelchair to a general medical ward: she seemed to have complex problems in every system that I enquired about. I despaired. I had millions of facts at my disposal but not enough pattern recognition to do anything the least bit helpful with them. Another thing I had yet to learn was that just sitting and giving her undivided attention for a couple of hours was quite possibly, in her case, as therapeutic as anything I could offer. But knowing that also involved recasting what I saw according to experience that at that stage I didn't have. I was desperate not to have missed a mechanism.

On the wards where I was trained, each general medical team would take it in turn to be the one to accept the medical emergencies that came in during a 24-hour period: this is known as being 'on take'. At the ward round the morning after being on take, as a House Physician, the lowest form of medical life, I would watch the Registrar, a qualified doctor with a middle rank in the team, having probably about three or four years of postgraduate experience, and having like me been up all night, move from

bed to bed, presenting to the Consultant, without notes, a concise history, findings on examination, and the results of any investigations and procedures that had been carried out, for each of about 25 patients. And I wondered how on earth he could remember so many details:

This gentleman is a 67 year-old retired miner, a lifelong smoker, with a family history of heart disease, a history of type II diabetes controlled by diet only, and hypertension currently poorly controlled by atenolol. He had recently experienced increasing fatigue and presented in Cas at 4 am, after his wife called an ambulance. She was worried, as he had become increasingly short of breath, was wheezing and showed signs of confusion. On arrival he was poorly perfused, with cold peripheries, BP was 130/95, he had a raised JVP, some wet rales, signs of cardiomegaly and an S3 gallop, a palpable liver edge at 2cm, and some pitting oedema. On direct questioning he admitted to a cough, but denied paroxysmal nocturnal dyspnoea. An ECG showed some Q waves, left axis deviation, but no ST elevation. His sodium came back at 124, potassium at 5.2 (we will repeat these later today), slightly elevated transaminases. We put him on nitrates, an ACE inhibitor, a furosemide drip and CPAP, and he is currently stable.

And then, after the Consultant had nodded and asked a few pertinent questions, and checked that an ‘echo was in the pipeline’, he’d walk on to the next bed and start all over again. How on earth did he do it? Was he a memory freak? To me it all seemed a bewildering mass of fairly unpredictable details.

But, like the chess player, he was using pattern recognition. There were half a dozen common possibilities here, and a number of less common ones. Enough details cohered to suggest what was most likely congestive cardiac failure; and once you have a template, you know what fits and what doesn’t – each becomes easy to remember for different reasons. All quite routine, really...

And then there were the astonishing feats of diagnostics involving rare and unusual conditions, which could be expected only from senior clinicians, those with the greatest experience. I have frequently had reason

to be genuinely in awe of the acumen of senior neurologists, general physicians and radiologists with whom I have worked.

Experts in any field need both to attend to the *Gestalt*, the picture as a whole, and, occasionally, to engage in (preferably limited) analysis. Why preferably limited? Because it has costs. It takes time, yes; but worse, it also changes its object, risks focus on areas that may be inessential, risks substituting something explicit and measurable for something much more important that is implicit and unmeasurable, and inevitably interferes with the functioning of expert skills, as we have seen in earlier sections of this chapter. As Whitehead said, such analytic forays ‘require fresh horses’, and must only be made at decisive moments.

Researchers into medical expertise have investigated the role of perception and memory in the decision-making ability of novice, as opposed to expert, physicians.¹⁰³ Physicians develop ‘illness scripts’ for diseases through experience.¹⁰⁴ They then verify the script against the information provided by the patient: as long as it matches the script, this is an unconscious process.¹⁰⁵ Experience, as in chess, changes what you see when you look, and how you relate it to what you remember having seen. Expert chess players’ fixations are to one side of specific pieces and near the centre of the board, whereas novices more often fixated a single piece at a time. Novices were found to activate only left hemisphere areas, whereas the attention paid by experts recruited the right hemisphere over and above the left.¹⁰⁶

Similarly, experienced radiologists were found to apply a ‘global’ analysis of mammography images in detecting breast cancer, their expertise reflected in a shift from detailed scanning of the image to a holistic, *Gestalt*-like perception.¹⁰⁷

A general surgeon in the US wrote to me to say that he found that he needed a way to keep tabs on a large number of patients, for whom all the technical assessments and investigations were carried out by his ‘residents’ (junior doctors). Every day he would stroll through the ward, doing what appeared to be social rounds. In reality he was comparing each patient’s face with how it had been the day before. ‘To my surprise’, he wrote, ‘I knew which patients were getting into trouble two or three days before even the best residents had a clue.’

Jerome Groopman has written a book-length study of the way doctors think. He notes that they blend *Gestalt* appreciation with deliberate analysis

in more problematic cases, and that this requires time.¹⁰⁸ But he is worried about the computer-like procedures involved in clinical algorithms:

Clinical algorithms can be useful for run-of-the-mill diagnosis and treatment ... but they quickly fall apart when a doctor needs to think outside their boxes, when symptoms are vague, or multiple and confusing, or when test results are inexact. In such cases – the kinds of cases where we most need a discerning doctor – algorithms discourage physicians from thinking independently and creatively. Instead of expanding a doctor's thinking, they can constrain it ... Statistics cannot substitute for the human being before you; statistics embody averages, not individuals.¹⁰⁹

Reliance on clinical 'instruments' for decision-making is fashionable. It is considered culpable, for example, not to administer one to a psychiatric patient so as to assess risk of self-harm. However, as I and my colleagues had long suspected, and confirmed through experience, instruments for predicting suicide turn out to be effectively useless. According to recent research:¹¹⁰

Risk scales following self-harm have limited clinical utility and may waste valuable resources. Most scales performed no better than clinician or patient ratings of risk. Some performed considerably worse.¹¹¹

These rote procedures induce complacency, encourage nursing staff to take their eyes off the ball, and to mistrust their intuitions. My most valued 'suicide detection instrument' was the acumen of an untrained auxiliary nurse with 30 years' experience on the wards. Auxiliary nurses often spend more time talking with and quietly observing patients than their trained colleagues; her having an 'uneasy feeling' about a patient was a sign worth heeding. Such intuitions are only useful, however, when they emanate from someone with experience, not from a novice.

The asking of routine questions and ticking of boxes can also make the patient feel reduced to a formula on a piece of paper, rather than truly attended to as an individual. This also makes the clinician seem more like a

technician than a nurse or doctor, thus lowering the clinical potential for helping an individual desperately in need of empathic engagement. And it lowers the morale of both clinician and patient. *Ars est celare artem* – or, to quote Valentine and Gabbard, ‘technique, in general, should be invisible. The therapist should be viewed by the patient as engaging in a natural conversational dialogue growing out of the patient’s concerns; the therapist should not be perceived as applying a stilted, formal technique.’¹¹² In my training, I watched my mentors effortlessly elicit aberrant psychic phenomena in a few minutes that I had failed to elicit in a considerably longer interview. If I eventually had a skill as a psychiatrist, it was to make sure that I covered every aspect of a patient’s life within an hour of what appeared to be a naturally unfolding conversation, so that patients would exclaim, ‘I have never spoken about this – you now know more about me than my partner [or parents or children].’ And to see the *Gestalt*.

There is much more to be said, but not here, about the obsession with algorithms, correct procedures and ‘evidenced-based medicine’, on the pitfalls of which Groopman is devastatingly clear.

Please note that, as ever, observing that we have become excessively reliant on a certain way of thinking or doing things, whatever it may be, does not imply there is no good in it at all, or that it should be wholly abandoned – only that it needs to be balanced with other elements, as just one strand in a coherent whole. Every sensible doctor will want to take into account the findings of clinical trials – though they have problems of reliability all of their own, as we have seen – but will also realise that such findings can only help shape, not substitute for, his or her own reflections on experience with various treatments.

Dreyfus and Dreyfus, like others, distinguish different phases through which the novice passes on the way to becoming a highly skilled expert. They delineate five, but for these purposes the detail does not matter as much as the clear overall shape. In brief, they show that in the first three phases, in different ways and to different degrees, having a procedure or algorithm to follow improves performance; but that in the last two phases such explicit modelling impairs decision-making and destroys the possibility of excellence. It enforces mediocrity. Intuition is what makes good judges, good physicians and good generals, as well as good teachers, pilots, poets, artists and leaders. Of course they need to have learnt and thought a lot – intuition is not in conflict with that, but indeed depends on it.

Nor is there anything that says that intuitions have to work fast: sometimes an intuition must guide us in a split second, but sometimes it unfolds over hours, weeks or months.

They summarise the expert's skill as 'pattern recognition, similarity recognition, common-sense understanding, skilled know-how, sense of salience and deliberative rationality.'¹¹³

It is not that experts are better at recall, or have a gift for analysis: we saw an example of that in expert chess players. It is those at an *intermediary* level that are best at explicit recall and reasoning, because, although they have more of an idea than the novice, they don't yet have the rich schemas of the expert.¹¹⁴ Just as we saw that understanding was achieved by innovative mathematicians and scientists through visual imagery, experts' judgments are strongly shaped by visual concepts derived from previous experience.¹¹⁵ This inevitably means that their explicit verbal accounts of how they proceed non-verbally and implicitly will not be accurate, and should not be taken as a model. The mathematicians and scientists we met in Part I were often at a loss to tell how they had arrived at their conclusions. In solving problems in geometry, experts do not pass through intermediate steps, but employ prototypical schemas.¹¹⁶ In physics, experts match schemas to features of the problem: novices and advanced students, by contrast, work from the bottom up, not having the schemas.¹¹⁷ Expert physicians, psychiatrists, nurses, judges, soldiers and businessmen may all reach decisions in ways that are not dissimilar.

There is a distinction to be made – and the Dreyfuses make it – between calculative rationality, which is what computers do, from the bottom up, and deliberative rationality, the last reflective stage for the true expert, in which reason may act on intuition.

When time permits and much is at stake, detached deliberative rationality of the type described [leading to a deliberately taken new perspective] can enhance the performance of even the intuitive expert. We reiterate, however, that such deliberation tests and improves whole intuitions. No rules or principles are used to arrive at conclusions, and so it is not the sort of calculative rationality used by the beginner or competent performer as a surrogate for intuitive understanding.¹¹⁸

Translating this into terms of hemisphere-typical function, the work of the left hemisphere is valuable, but should, as always, be secondary to that carried out by the right hemisphere. And Dreyfus & Dreyfus might have added that only intuition tells us *when* to invoke the specifically analytic processes – there are no rules for that, either.

Both explicit and implicit knowledge contribute to adaptive decision-making.¹¹⁹ Why ever would they not? Both meet in pattern recognition, the appreciation of the *form* of something, not just the pieces packed inside the form. This is where *logos* and *mythos* meet.

But unfortunately the logically fettered mind can never come to know what it is it doesn't know:

To the extent that junior employees using expert systems come to see expertise as a function of large knowledge bases and masses of inferential rules, they will fail to progress beyond the competent level of their machines. With the leap beyond competence to proficiency and expertise thus inhibited, investors in expert systems may ultimately discover that their wells of true human expertise and wisdom have gone dry.¹²⁰

There is a difference between knowing a poem by heart and knowing where to find it in a book. There is a difference between the embodied experience (and a lifetime's reflection on it), that distinguishes a capable judge or a capable physician, and the following of flow diagrams or application of rules that could be done by a clever teenager. Knowledge that is so far assimilated as to have become part of us changes us, and enables us to be competent practitioners. A doctor is not infallible, but neither is a machine: the more the doctor's knowledge is externalised – outsourced to the following of an algorithm or a computer – the more deskilled he or she becomes. And a deskilled doctor is no good to a patient: something more like an investment adviser, able to summon up figures on a screen, deliver the news of what is in your account, and sell you the package the machine advises.

Doctors have not been as closely studied as nurses. In the world of nursing, Patricia Benner notes that becoming an expert means shifting from

abstract principles to seeing intuitively the patient before you in relation to other real-life experiences, and noting similarities and differences.

She also emphasises three other features of expertise, each of which can be seen as a shift from left hemisphere to right hemisphere 'mode': a change from viewing separate pieces of information to perception of situations as a whole; a 'fluid, flexible' performance; and the 'passage from a detached observer to an involved performer, no longer outside the situation but now actively engaged in participation'.¹²¹

Benner recognised that nursing was poorly served by theories developed in the academy, and introduced the (nowadays) revolutionary idea that the practice itself could and should inform theory.¹²² As a result her ideas are open to criticism from more conventional quarters for not being quantitative, and for using narratives.¹²³ Remember once again that the left hemisphere is more interested in quantification than qualification, and distrusts narrative – indeed has difficulty understanding and seeing the point of narrative at all. Equally, because her model relies on experience, which partly comes with age, rather than rules which any person (or machine) could follow, it has been argued by some that she represents a step back into tradition and authority in nursing.¹²⁴ Though the left hemisphere's theory may dictate that each person is effectively the same as and replaceable by any other member of the category, the right hemisphere is aware of individuals as individuals and that learning comes from living. The words 'tradition and authority' are here being used as boo words for what is merely common sense – namely that we learn best from those who have more accumulated experience, and have had more time to reflect on it, than we have. Not to recognise that fact is a sort of self-inflicted disability.

In fact such clinical skills are inevitably those of a real individual, here the skilled nurse, in relation to another real individual, the patient in question. It is as much about knowing the patient, as it is about knowing facts.¹²⁵ And, interestingly, experienced nurses recognise not just the importance of their own intuitions, but the importance of the patients' own intuitive feelings.¹²⁶

A number of studies have established that intuition in nursing is real and indispensable.¹²⁷ Attending to past experience improves nurses' judgment.¹²⁸ It is not mystical or somehow 'unscientific'.¹²⁹ Many nurses in practice feel that they should not be using intuition in reaching decisions and find

that it is often denigrated by managers, their own colleagues and doctors.¹³⁰ However, a lack of intuition means that patients may receive inappropriate or incomplete care; and, despite formal discouragement, most nurses persist in putting their intuitive knowledge to use.¹³¹ What is more, incorporation of intuition into judgment increases with expertise – which is as it should be, since the gut feelings of novices should not be equated with experienced intuition.¹³²

What is involved appears to be a rapid process of perception, happening below the level of conscious awareness, and bringing to bear neither abstract cognition on its own, nor the promptings of feelings alone, but their fusion in an intelligent understanding of the situation as a whole. The process is fast and frugal, in Gigerenzer's phrase, and can work with only partial information.¹³³ The reader will recall from Part I that that, too, is a classic hemisphere difference: the right hemisphere is superior where information is only partial, or partially degraded – which is mostly the case in real life.¹³⁴

CONCLUSION

Intuition appears to be something that, while inevitably fallible, is often more reliable, much quicker, and capable of taking into account many more factors, than explicit reasoning, including factors of which we may not even be consciously aware. It also underlies motor, cognitive and social skills, and is the ground of the excellence of the expert. The attempt to replace it with rules and procedures is a typical left hemisphere response to something it does not understand – a response that is, alas, powerfully destructive. We inhabit a world in which reason is needed more than ever before, yet in which reason is so narrowly conceived that it drives out true understanding. For that we would have had to learn respect for the power of intuition, not as opposed to reason, but as both grounding it, and the means for it to fulfil its potential in making judgments in life.

In *Also Sprach Zarathustra*, Nietzsche wrote: ‘The body is a great sage, a *Many* with *One* purpose, a war *and* a peace, a flock *and* a shepherd ... There is more sense in thy body than in thy best wisdom.’¹³⁵ He saw that what he calls the ‘body’ (namely, all that lies outside the conscious stare of the left hemisphere) understands a purpose that includes the free and the determined together, conflict and harmony together, multiplicity and unity as one; and understands that opposites coincide. Words that are worth bearing in mind throughout the rest of this book.

THE UNTIMELY DEMISE OF INTUITION

My concern is with a movement or programme which is aimed at ultimately bringing the body entirely under control of the mind.

—Patrick Curry¹

IN OUR DISCUSSION OF SCIENCE AND REASON AS APPROACHES TO TRUTH, WE came time and again upon the implicit belief that truth could really be grasped only if the embodied human being, with its distastefully irrational feelings, prejudices and instincts could somehow be got out of the way. According to this belief, human beings are inherently fallible and it is this human element that is the source of error; only by expunging it can there be any hope of approaching truth. Of course human beings are indeed fallible, but this false belief that we must transcend the human in order to approach truth is both in itself irrational, and leads, as I suggested, to exaggerated claims for the truths of science and to a narrow sense of reason that equally misleads. It is, I'd suggest, this allergic attitude to the human and to inherent human fallibility that lies at the heart of the mistrust of intuition. For, as we have seen, intuition draws the products of its understanding straight from the body and places them instantly on the table, as it were, without the chance for the left hemisphere first to clean it all up, wash off the traces of the human innards and re-present it all as something purer, free from the stain of the human and so more 'objective'. Intuitions come from the 'guts', for heaven's sake: if one is going to look for truth from such a

source one may as well put one's faith in the Pythia's reading of the entrails of a chicken.

So it is not surprising that psychologists like thinking up what one might call 'illusions of intuition', cognitive equivalents of the chequerboard at the beginning of the previous chapter, to show how foolish we would be to trust in intuition. It's an observation worth pondering that this may have little to do with how psychologists, philosophers and other theorists actually behave in real life. As philosophers Andrew McGee and Charles Foster put it:

We [both authors are academics] spend a fair amount of our time with people who, for money, prestige and because they think it's the right thing to do, try not to be intuitive. Universities are full of them. But here's the thing: they are only non-intuitive at the office – and only very, very inconsistently there. As soon as they push open the Faculty door and leave for the real world of relationship and sick children, they're immediately and unavoidably back in the atavistic world of the Upper Palaeolithic that they officially fear and repudiate.²

By definition, psychologists belong to a class of people who generally like taking things apart to see how they work, and therefore intuitively dislike the idea that results can be had without working explicitly through the logical steps. And of course they are right – up to a point. It would be as foolish to assume that intuitions will always lead to the right answers as to assume that pure rationality will.

Intuition is capable of fooling even those who might be regarded as supremely rational and therefore most immune to it. Take this, for example:

Fig. 35. The Monty Hall Dilemma

It is called the Monty Hall Dilemma, named after an American TV game show, a problem that defeats some of the world's greatest mathematicians, and is arguably better solved by pigeons than humans. So why do I say that conscious focussed reasoning works?

The problem is simple and can be briefly and completely stated. A contestant chooses one of three doors, knowing that behind one there is a smart new car, but behind each of the other two there is a mangy goat: there is no way of telling which. After the contestant selects a door – at this stage still unopened – the host (Monty Hall) reveals a goat behind one of the *other* two doors. The contestant is then given an opportunity to switch from his or her original choice to the other still unopened door. Most individuals decline – despite the fact that switching would double their chance of winning.

Double their chances? How could it possibly change them at all?

Here's the explanation:

The probability that a participant will randomly select the door with the prize on the first guess is one in three, because there is one prize and three possible locations. If the initial selection is the winning door, then after the host reveals one goat, it follows that the second goat must be behind the remaining unselected door. Thus, on one-third of all trials, staying wins and switching loses. In contrast, the probability that a contestant will not choose the door with the prize

on the first guess is two in three. If the contestant's chosen door conceals one goat, and the other goat has been revealed, then the remaining door must conceal the prize. Thus, two-thirds of the time, switching wins and staying loses.³

If you still find this difficult to comprehend (and I assure you it is correct), take some comfort from the fact that even prodigiously clever mathematicians find this hard to get. They seem to be fixated on the idea that the facts of the situation haven't changed. True. But our information about the situation *has*. And since a rational choice should be based on all the information, not just the information we started out with, it makes sense to change when you know something new that alters the odds. Paul Erdős, one of the greatest mathematicians of the last hundred years and a specialist in probability theory, thought it was impossible that switching made any difference, and got angry when a colleague tried to explain it to him – though some days later he conceded the point.⁴

The problem was submitted to Marilyn vos Savant for comment in a magazine column she ran for many years looking at mathematical problems:⁵

She answered the question of 'to switch or not to switch' by saying, 'yes, you should switch', and gave her explanation. In a later column she published signed letters from 4 PhDs (some quite nasty and sardonic) which severely chastised her for misleading and corrupting the public. Later she gave an alternate explanation. In a still later column she published letters from another 5 PhDs, who all called her an idiot.⁶

In a simulated lab version, humans can be brought to a point where they get the idea that they are better to switch, but they still only actually switch about two-thirds of the time, because they indulge in what is called 'probability matching': they try (wrongly) to match their awareness that they will win only two-thirds of the time, by *doing the right thing only two-thirds of the time*, so that they score only a little above chance. The sad fact of the matter is that pigeons do better: they learn that they do better to switch every time, and thereby win 67% of the time. And the most likely

reason they do better is that they learn from experience, and don't let 'reasoning' get in the way: after 200 trials, humans largely failed to adopt the optimal strategy that the pigeons had quickly mastered.⁷

This has relevance to the hemisphere hypothesis. In an unconnected experiment with split-brain patients, the subjects were asked to guess which colour, red or green, was going to be displayed next, in a series where there were four times more green than red lights displayed. The right hemisphere saw – like the pigeon, though unlike the pigeon it saw it immediately – that the way to get the best score was to choose green every time, leading to a score of 80%; the left hemisphere chose green at random, but about four times more often than red ('probability matching'); which sounds smart, but is illogical, since you have no way of knowing what the next colour will be. As a result of being smart, the left hemisphere scored little better than chance. It had developed a 'rule', but the rule was wrong.⁸

What can one learn from this? First, that reasoning can of course be helpful, but only if you can be certain your reasoning is right – which apparently even mathematical geniuses can't. Failing that, reasoning will mislead you: and being attuned to what experience tells you (pigeon fashion), without letting the attempt to reason get in the way, is safer – though it may take a while longer. Thinking slow?

So of course it is true that intuitions can lead us astray. But does that mean that they are worthless or, at the very least, dangerously unreliable? The case for believing so seems to derive from suspicion of the apparent instantaneousness of intuitive knowledge. It comes unexamined. It arrives without having been put through the wringer of critical scrutiny. The truths it claims to offer have in some mysterious way been cooked up beforehand, 'pre-judged'. In short, intuition peddles prejudices not truth.

That is a charge we need to take seriously. I will argue, however, that this account fails to invalidate intuition because it is based on a number of illusions, quite apart from the fact that intuition is clearly a far richer phenomenon than any form of prejudice. These illusions include: that human beings can *ever* avoid prejudice, in the sense of forming judgments from experience of the past to help them deal with the future; that an analytic training in science, or education in modern Western academic practices reduces the likelihood of such prejudice; that prejudices are largely mistaken; that prejudice inevitably issues in bias; that bias is not normally subject to correction as soon as a judgment can be made on more

than the barest outline; and that even if we were able – which clearly we are not – systematically to substitute reason for intuition, we would be guaranteed against bias.

In the 1960s and '70s academic psychology became dominated by an urge to demonstrate that human ways of thinking, dealing with aspects of experience in memory, and understanding the world through intuition, were radically flawed. This coincided with the espousal of the idea of the brain as a computer, a calculating machine, encoding, storing and retrieving data from memory banks; 'by the standard of decontextualized and literal processing of information on a computer hard disk, the human mind was a poor performer', says psychologist Brady Wagoner.⁹ We were seen as lazy, inefficient, 'cognitive misers'. As he points out, however, 'this focus on identifying error and distortion obscured important, non-mechanical dimensions of mind and the study of accuracy as more than what a computer does with information.' Part of the legacy has been a common conviction that compared with an ideal form of computing that would be carried out by a machine, we are prejudiced – and therefore almost bound to be wrong in making judgments.

PREJUDICE VS BIAS

I quoted earlier Douglas Hofstadter to the effect that ‘isolated reasoning is impossible, because reasoning depends on a prior setting-up of a system of concepts, percepts, classes, categories – call them what you will – in terms of which all situations are understood. It is there that biases and selection enter the picture.’ ¹⁰ Necessarily so – not just by an unfortunate accident. And the fantasy that machines could somehow produce unbiased outcomes that human beings, flawed as they are, can’t, is, to say the least, naïve. Partly, there is no such thing as avoiding a point of view, which is why it is important that the fact is recognised; and that it is recognised that the point of view is the result of reason combined with thoughtful experience, not just any old bias someone happens to have at the time. A machine that ‘learns’ has no thought or experience, but incorporates any imbalances or biases in the data from which it ‘learns’ as well as those that will be built into the ‘decision-making’ processes coded into it by human programmers – who are not necessarily any better at spotting either kind of bias than anyone else. Such systems learn the biases of their programmers and trainers. A dyslexic naturalist friend of mine asked Siri how to spell *tiercel* – the word for a male hawk, as she explained to Siri. Siri replied to the effect: ‘What’s all this about gender? It shouldn’t matter which gender it is.’

If we are foolish enough to imagine that machines avoid bias, the now concealed bias is all the more dangerous. We also know that interactive systems tend to gather information from and produce it for people who think in similar ways, insidiously compounding biases: this tendency, well known to be built into internet search mechanisms, and reinforced by the ‘blogosphere’, produces potentially toxic ‘bubbles’ or cocoons of bias, in which people feel justified by the fact that they only ever hear confirmatory points of view. We overestimate the sameness of out-groups compared with our in-group. ¹¹ Since the right to express competing and contrasting points of view is the very core of democracy, and since hearing competing and contrasting points of view is the basis of education, and therefore, once again, of an informed democracy, and since without it creativity and all forms of innovation quickly wither away, this is of first-rank importance.

Taking a much broader view of the topic of pre-judgments (*Vorurteile*), in his magnum opus *Truth and Method*, the philosopher Hans-Georg Gadamer urged that prejudice-free knowledge is neither possible nor desirable. Gadamer argues that prejudices are not necessarily vicious, and that the Enlightenment had a ‘prejudice against prejudice’.¹² Prejudices cannot be done away with: they are replaced only with other prejudices, sometimes better, sometimes worse, and we should bear in mind that the more historically unusual they are, the less we have to go on in assessing their accordance with reality. It is not our duty to be without prejudices, but to be aware of them – including the prejudice against prejudice – and examine them unremittingly, abandoning one prejudice in favour of another if we find the first does not accord with experience. It requires experience and good judgment to know when to retain, and when to reject, a prejudice. We cannot possibly make all – or perhaps any – of our own judgments from scratch: the idea that it would be feasible, never mind commendable, for us to reject completely the accumulated wisdom of humankind, and start again on the basis of our own limited knowledge and intellect, is a species of arrogant folly. On the contrary, writes Gadamer scholar Lauren Barthold,

prejudices are the very source of our knowledge. To dream with Descartes of razing to the ground all beliefs that are not clear and distinct is a move of deception that would entail ridding oneself of the very language [since language embodies a tradition of thought] that allows one to formulate doubt in the first place ... To affirm, as Gadamer does, that one can never escape from one’s tradition, does not mean he is insisting we endorse all traditions writ large ... accepting the fact that one can never entirely reflect oneself out of tradition does not mean that one cannot change and question one’s tradition. His point is that in as much as tradition serves as the condition of one’s knowledge, the background that instigates all inquiry, one can never start from a tradition-free place. A tradition is what gives one a question or interest to begin with.¹³

And a tradition is a body of beliefs which exists apart from and prior to any particular set of circumstances – prejudices, if you like; except (and this is Gadamer’s point) to call them such is to invite unthinking dismissal,

given the intellectual tradition to which we now belong. Even those who revolt against tradition are doing so as part of a, now venerable, tradition – that of the seventeenth- to eighteenth-century Western Enlightenment. You cannot *not* belong to a tradition.

But – here’s the point – a tradition is never static: if it were to become so, it would die. It is there not just to oppose change but to inform it and guide it. It is a living thing, a process of change in response to new circumstances. It is reverberative and responsive, not linear and fixed: forever in flow. Nonetheless, there is a difference between organic change and forced or abrupt change, as there is a difference between training a climbing plant and cutting it off, or uprooting it. A tradition changes by being born anew in each member of the community that shares in it. It is, above all, lived:

To embrace a tradition is to make it one’s own by altering it. A passive acknowledgment of a tradition does not allow one to live within it. One must apply the tradition as one’s own.¹⁴

In this respect, it is obvious that we are each only what we are, only think what we think, only believe what we believe, and love what we love, against a background of shared meanings within a culture and a landscape from which, though individual, we stem, in which we are never wholly separate one from another, and in terms of which ‘meaning’ has meaning. The rightful rejection of the Cartesian fantasy of an isolated, decontextualised, rational mind, hopping around the universe accessing uncontaminated truths, is at the heart of the last hundred years of philosophy in Europe, and is what Heidegger, Scheler, Merleau-Ponty and others were striving to achieve and to communicate. Not to have affections, not to have affiliations and loyalties, not to have love, but only reason to act for us in understanding what we do and who we are, is literally a form of madness. Nonetheless, Jung’s concept of the collective unconscious and its archetypes is another way of conceiving this broad implicit understanding on which we depend, one that takes up the individual tradition and, without eroding its identity, sets it in communion with other traditions. One of the striking things about research into implicit beliefs, whether one calls them intuitions or prejudices, is how constant they are across widely different cultures.

A prejudice literally means a pre-judgment. We inevitably make generalisations in order to guide action when we have little to go on, or little time to weigh up all the factors in a deliberative fashion, which is almost all the time. We couldn't survive if we did not, since having time to deliberate all the aspects of a situation is rare. Nor would we survive if the generalisations were not reasonably reliable, even though they are primarily of practical value, and cannot be other than highly fallible guides to the truth of particular instances. The knowledge that tigers are dangerous has survival value, and is not disproved by one friendly tiger, though it's not true in that particular case. The knowledge is drawn from general experience in advance of the situation, not from the particulars of the actual situation; which does not in itself make it unintelligent, imperceptive or factually wrong. In fact it would be foolish – indeed impossible – not to draw conclusions from experience to date. Thus pre-judgments are rational. I would argue that prejudice is usually a derogatory term for what we cannot help imbibing from experience, even if we wanted to, and indeed *must* imbibe if we are to live as fully functioning human beings.

However, prejudices can be based on ignorance, rather than experience; and even one based on experience is, obviously, ugly and harmful when it is incommensurate with that experience, or, very importantly, substitutes the category for the individual. Prejudice and bias are not the same thing. But, as I hope to show, you can be prejudiced without being biased – which is just as well, because otherwise unbiased judgments would be impossible, since we all have prejudices. In many cases, however, prejudice and bias concur. Some degree of bias in favour of what you believe, is inevitable – otherwise you wouldn't believe it, would you?

Such a bias has, as it turns out, nothing to do with intelligence, as you might expect. A large body of research suggests that, to quote one recent paper, 'high intelligence is no inoculation against my-side bias'.¹⁵ In other words, intelligent people are every bit as likely to have biases as less intelligent people – and to deny their own prejudices. Nor does the quality of causal reasoning about an issue relate to intelligence, apparently.¹⁶ Being a scientist doesn't help, either, by the way: there is ample evidence, some of which we have already looked at, that scientists are no less prone to bias than anyone else. Indeed, some evidence shows that people with more education are *more* likely to cling to ideological beliefs in the teeth of evidence.¹⁷ They also express less racist views, but show more implicit

racially aversive responses (ones that cannot be controlled): they say one thing, but believe another.¹⁸ And interestingly, an investigation into belief in pseudoscience found that it was associated with analytic, but not intuitive, thinking style:

After controlling for demographic variables, level of science literacy and cognitive ability, both analytic and intuitive cognitive styles positively predicted paranormal belief. Belief in non-paranormal pseudoscience associated positively with analytic, but not intuitive style.¹⁹

On the topic of scientific bias, an aside: the astonishing apathy about climate change is not a matter of scientific ignorance, more about bias. Those members of the public with the highest degrees of science literacy and technical reasoning capacity were not the most concerned about the issue, but they were the ones with the most polarised views. ‘This result’, write the authors of the study that reached this conclusion,

suggests that public divisions over climate change stem not from the public’s incomprehension of science but from a distinctive conflict of interest: between the personal interest individuals have in forming beliefs in line with those held by others with whom they share close ties and the collective one they all share in making use of the best available science to promote common welfare.²⁰

Groupthink so often rules, because membership of the ‘in’ group is more important than using one’s critical faculties, and even *questioning* an established fashionable idea can lead to exclusion and vilification.

Groupthink is the danger. Groupthink will lead people to mistrust both their senses and their intuitions. In a now famous experiment, subjects were told that their vision was being tested, and asked to say which line, in an array of three, was closest in length to a target line.²¹ The answer was obvious. However, stooges were set up to give the same, obviously erroneous, answer – after which the naïve test subject, in a third of trials, fell in with the majority, despite knowing it to be false (though, chillingly, some participants even started to believe the majority were right). This is

one reason why it is of the utmost importance that there be dissenting voices, since the presence of even one dissenting voice reduced conformity by 80%.²²

In fact, being less dispassionate – more emotionally involved – with a topic leads to your being *more* willing to listen to evidence, rather than less. It matters to you more. It turns out that when people have low investment in an argument, neither strong nor weak arguments are persuasive. Their minds are made up, and no argument shifts them. But when they are highly involved with an issue, both strong and weak arguments have a significant effect, in the way that you might hope: weak arguments making people more entrenched, but strong arguments resulting in a shift of position.²³ So motivation encourages a more thorough evaluation of the evidence with a genuine commitment to find what seems truest. However, as might be expected, strong arguments are only persuasive if people are given some deliberation time before being forced to give a reaction.²⁴

Evidence suggests that speaking your native language promotes contact with the emotional depths of experience and that speaking only in a second language promotes a dissociation from them:²⁵

Losing your native tongue unmoors you not only from your own early life but from the entire culture that shaped you. You lose access to the books, films, stories, and songs that articulate the values and norms that you've absorbed. You lose the embrace of an entire community or nation for whom your family's odd quirks are not quirks all. You lose your context.²⁶

In an era when a simplified, to some extent denatured, version of English is becoming the lingua franca of all debate, this is troubling. And the disconnexion can be devastating. In those First Nations of British Columbia communities where fewer than half of the members could converse in their indigenous language, young people killed themselves six times more often than in communities where the majority spoke the native language.²⁷ It was remarked that they had lost cultural continuity, and risked losing 'the thread that tethers together their past, present, and future.'²⁸ As I write, such a fate has become a reality for indigenous people of every culture, including those of so-called 'developed nations'.

Julie Sedivy, a Czech-born Canadian, remarks of her father, who deplored his family's espousal of English:

I watched as my father grew more and more frustrated at his powerlessness to pass on to his children the legacy he most longed to leave: a burning religious piety, the nurturing of family ties, pleasure in the music and traditions of his region, and an abiding respect for ancestors.

To have no particular predilections is impossible. The difference is not between those who have such predilections and those who don't, but between those who know they have them and those that are ignorant that they have. And these are the dangerous ones: those that think they lack prejudice.

They exemplify what is called the bias blind spot. Fairly obviously, believing you are less biased makes you more dangerous, because you are less open to advice or to alternative views. And it is widespread. In one study series, only one out of the 661 participants judged himself or herself more biased than the average person.²⁹ Moreover, according to the same series of studies, believing yourself to be unbiased is not related to intelligence (or to education, self-esteem, age, sex or race).³⁰ 'If anything, a larger bias blind spot was associated with higher cognitive ability', conclude Richard West and colleagues, leading researchers in this area.³¹

But prejudices do not *have* to issue in bias. Even an unbiased person will have accumulated past experience, and if, as seems likely, experience does not lead to a conclusion that there simply are no group differences to observe, a pre-judgment is inevitable, and to ignore it entirely is irrational. However, you can and must also take such a pre-judgment into account when making a judgment, so as not to be biased. Prejudices, like reasonings, are only accidentally, not intrinsically, mistaken. As Lee Jussim, Professor and Chair of the Psychology Faculty at Rutgers, points out, if members of motorcycle gangs have higher convictions for acts of violence than do ballet dancers, and men have higher rates than women, we would be simply irrational not to be more concerned by an encounter with male bikers than ballerinas on an ill-lit street at night.³² We are made to feel that such generalised judgments based on knowledge or experience are based on

nothing solid. But they could just as well be called judgments as prejudices.

A common form of objection to any generalisation is to point to examples that contravene it. But on its own this argument has no force: a true generalisation of any kind is fairly obviously not to be dismissed on the grounds that it is not invariably so. Of course it is true that men are taller than women; and of course you can find women – many of them – who are taller than many men. And of course the second does not contradict the first. So it is with all generalisations.

It is itself a prejudice that members of all groups must have the same qualities: even if it were not disproved by experience, the assumption would be irrational. Prejudice against stereotypes, according to some psychologists, is itself an example of prejudice in the face of evidence to the contrary. Examples of silent false assumptions include, according to the sociologist and philosopher Gustav Ichheiser (incidentally a man who knew what malign prejudice could mean: as a Jew, he had had to flee Hitler's Germany): 'people are essentially alike'; 'to think that they are different is prejudice'; 'cultures make no difference to how people think and behave'; 'prejudices, rather than differences, are the main cause of intergroup tensions'; 'stereotypes concerning characteristics of cultural and racial groups must be false'; and 'the layman is prejudiced, but the social scientist is not'.³³ According to a substantial body of evidence, stereotypes are, in fact, surprisingly accurate (see below).

According to Jussim, whose book *Social Perception and Social Reality*, published by OUP in 2012, is the most substantial examination of the area I can find, we assume that, because it has historically produced palpable social wrongs, prejudice must be factually wrong. Looking for the empirical evidence underlying such assumptions revealed that 'there was nothing there, just a black hole ... Stereotypes are almost never perfectly accurate, and they are sometimes highly inaccurate', he says. However,

stereotype accuracy is one of the largest and most replicable findings in social psychology. Over the last 30 years or so, rigorous social science assessments of the accuracy of stereotypes have been steadily rolling in – and, usually (though not always), they show that people's beliefs about groups are pretty (not perfectly) accurate.

Pointing this out has often evoked harsh yet scientifically vacuous responses ...³⁴

In statistics, there is a measure of the strength of a correlation known as the Pearson correlation coefficient (r): the closer r is to 1.0, the more reliable the correlation. To set things in context, an analysis of 25,000 studies, involving 8 million people, across the whole of social psychology research revealed that the most typical r value is 0.21.³⁵ By contrast, the correlations between stereotypes and criteria range from 0.4 to over 0.9, and average almost 0.8 for cultural stereotypes (the correlation of beliefs that are widely shared with criteria).³⁶

Stereotypes of age,³⁷ sex,³⁸ and race³⁹ have all been repeatedly shown to be remarkably reliable, and transferable across cultures.⁴⁰ Corinna Löckenhoff⁴¹ at Cornell has shown, in a paper with 50 authors, that a study of 3,323 individuals across 26 nations, when applied to males and females, demonstrated that the standard survey items captured sex stereotypes in personality over different generations and cultures that correspond to established sex differences: ‘perceptions of actual sex differences may play a more important role than culturally based gender roles and socialization processes.’⁴² Robert McCrae, another leading researcher in the field, writes that ‘consensual stereotypes of personality traits of different age groups and sexes have proven to be remarkably accurate.’⁴³ Interestingly, it seems that stereotypes of male/female differences are accurate but understated (for the curious reader, the first author on each paper here is a woman), whereas stereotypes about political ‘right/left’ differences are accurate but overstated.⁴⁴ Perhaps only our stereotypes of how much other groups engage in stereotyping compared with our own are mistaken.⁴⁵

There is a well-known argument that the reason for objective measures coinciding with prevailing beliefs is what might be called ‘self-fulfilling prophecies’: people conform to expectation. Jussim addresses this at length in the book referred to, and argues, I think convincingly, that this is not generally the case. More of a problem, it seems to me, is knowing how to be sure that the ‘objective’ correlate with which one is comparing is itself truly free from bias. This is a problem for those who wish to claim we are deceived in our prejudices as much as for those who wish to claim we are not. The danger is always of a circular process in which results favouring

one point of view are compared with results that also favour that point of view, and found to be astonishingly concordant. Of course, this problem is generally acknowledged in the design of experiments investigating the validity of prejudice, and often, but perhaps not always adequately, taken into account.

So prejudices are not necessarily wrong. What is wrong is to be biased in any individual case by your prejudice. And crucially and very fortunately – our capacity to avoid prejudicial bias when judging *individual cases* is nothing like as limited as is often suggested. In fact it is remarkably good.

It is not true that we don't compensate for prior beliefs in particular cases, and we may even overcompensate for them. According to a meta-analysis of this issue, carried out by the distinguished social psychologist Ziva Kunda and the philosopher Paul Thagard, when individuating information (information about the individual in question, regardless of stereotype) is clear and relevant, its effects are 'massive', with an r of .71 (making it one of the most robust effects in social science), and stereotype effects tend to be 'weak or non-existent'.⁴⁶ In general, therefore, based on an overview of more than 300 experimental studies and a smaller number of naturalistic studies, stereotypes are found to have only very modest influences on our perception of actual individual cases. Jussim and colleagues report:

Considerable evidence has accumulated that people usually (though not always) apply their stereotypes in a largely rational manner, relying heavily on stereotypes in the absence of clear individuating information, but relying heavily on relevant individuating information when it is available ...⁴⁷

Putting it more technically, the effect of stereotypes is 'one of the smallest in social psychology': 0.1. The effect of individuating information is 'one of the largest': 0.7.⁴⁸ They conclude:

To be sure, evidence of stereotype inaccuracy clearly exists. But it exists amidst a body of literature that also includes abundant evidence of stereotype accuracy. In 2014, when this chapter was written, it is only possible to maintain blunt declarations of

stereotype inaccuracy by cherry-picking studies demonstrating inaccuracy, systematically ignoring studies that demonstrate accuracy, and employing double standards that permit the derogation of accuracy [of] studies that are at least as methodologically sound as inaccuracy studies. Thus, our final recommendation is that researchers simply stop declaring stereotypes, in general, to be inaccurate ...⁴⁹

A report commissioned by Britain's Ministry of Justice from Cheryl Thomas, Professor of Law at University College London, and the author of *Diversity and Fairness in the Jury System*, is of relevance here.⁵⁰ She was invited to address concerns about racial prejudice in juries. In her 2010 report entitled *Are Juries Fair?*, also commissioned by the Ministry of Justice,⁵¹ she found that all-white juries in Britain are not more likely to convict black defendants, or to acquit white defendants accused of racist assaults. In fact, it seems all juries, black or white, are more likely to convict white defendants, and notably, white juries in a racially mixed area were 'significantly more likely to convict the white defendant when he was accused of assaulting a black or minority ethnic victim compared to a white victim'. Thomas also refuted earlier findings – based on a much smaller case sample – about rape cases. She found juries' conviction rate in rape cases to be about 55%, higher than for attempted murder, manslaughter and GBH (grievous bodily harm, the most serious level of physical assault under British law). While accepting that the low proportion of rape allegations resulting in conviction remains a real concern, she suggests that this has little to do with juries' perceived unwillingness to convict.

I wouldn't want to make too much out of all this: there are a number of caveats to enter. Of course we can be blinded by prejudice. Nor does Jussim claim, obviously, that there are no wrong prejudices, nor that there are never adverse consequences to prejudice – just that our view that they are usually wrong is false. He does not claim there will not be individual studies that are discordant with his conclusion, since he is basing conclusions on meta-analytic overviews of the research. Nor does he have anything to say about why it is that differences between groups exist, a quite separate issue, or whether the indicators he is using reflect enduring differences, or just how things stand at a moment in time. But just because we have a prejudice against prejudice is not a good enough reason to ignore the evidence.

We also make judgments of fact very swiftly: are they reliable? Some people object to the natural human capacity to judge character from faces: perhaps inevitably someone has coined the term 'face-ism'.⁵² Such judgments will often be wrong, of course, so whenever one has more to go on one should not simply rely on judgments based on the face (just as one should always seek the widest range of information practically available in making any judgment). However, as has been repeatedly pointed out by scientific experiment, we are quite capable of judging character from the face, even if the effect is not very strong.⁵³ People prefer elements on which they can pass a conscious judgment, such as hair or clothing, but these elements impair the quality of their first 'instantaneous and effortless' judgments based on the face.⁵⁴ Such *Gestalt* judgment is significantly better than chance at exposures of around a tenth of a second (though not at 1/30th of a second).⁵⁵ It is based at least in part on experience; thus accuracy at the task increases 2.5 times between the ages of 13 and 18.⁵⁶ The effect operates equally well in a cross-cultural context.⁵⁷ Female subjects 'may exhibit an evolutionary-based overestimation' of 'defectors', ie, understandably be more cautious in judging someone trustworthy.⁵⁸

We are highly accurate at judging age, sex and race with very brief exposures (around a tenth of a second).⁵⁹ But we are also much better than chance at judging more ambiguous categories, such as sexual orientation (even when subjects make an attempt to disguise it)⁶⁰ and political affiliation. A meta-analysis careful to allow for confounding effects found that 'aggregating across tens of studies and hundreds of effects, people were found to be significantly more accurate than chance in categorizing members of perceptually ambiguous groups'. The total combined effect suggests that approximately 64.5% of targets would be correctly categorised, compared with the expected 50% by chance alone. This yields an *r* of .29, which, as the authors point out, is better than the average for social sciences results.⁶¹

The time course of action of a prejudice is clearly instantaneous, though it may take years to evolve.

As far as hemispheres go, stereotypes are aggregates of experience, and depending on how you look at them, could be associated more with either hemisphere. Their genesis requires pattern recognition and social sensitivity (more typical of the right hemisphere); their application may involve

conclusions that have been jumped to (more typical of the left hemisphere). The left hemisphere plays a more prominent role when targets are considered as examples of generic social categories (eg, men or women, black or white) rather than unique individuals.⁶² People who have difficulty dealing with and being alive to social relations may fail to detect reliable patterns of difference and rely on abstract reasoning to conclude that there therefore are none. However, there is evidence that the right frontal area has a very important role in inhibiting *acting* on prejudice in any one case. The retrieval of conceptual knowledge typically involves the left inferior frontal gyrus; by contrast, dealing with the individual case, and deciding whether this case fits the general concept, depends on the right inferior frontal gyrus. Activity in the right inferior frontal gyrus is seen when subjects are judging whether sex-stereotyped traits apply or not to a series of male and female individuals (as compared with traits that were unrelated to sex stereotypes).⁶³

The right inferior frontal gyrus has, in fact, a role in inhibiting prepotent responses across many domains.⁶⁴ Most findings indicate that activity in the left lateral prefrontal cortex is linked to the implementation of action, whereas activity in the right lateral prefrontal cortex is linked to inhibition of action.⁶⁵ ‘This pattern of lateralised function – stereotype retrieval and implementation on the left and response inhibition on the right – suggests a useful distinction in the processes through which stereotypes are applied in behaviour’, according to neuroscientist David Amodio.⁶⁶

Overall, then, one thing is clear: the left hemisphere is more prone to bias than the right.

Finally, the idea that reason acts as the ‘cleaner-upper’ of the messy, gut-sourced prejudices produced by intuition is itself an illusion. In their seminal paper referred to earlier, entitled ‘Why do humans reason?’, cognitive scientists Hugo Mercier and Dan Sperber argue that while

reasoning is generally seen as a means to improve knowledge and make better decisions ... much evidence shows that reasoning often leads to epistemic distortions and poor decisions ... reasoning pushes people not towards the best decisions but towards decisions that are easier to *justify*.⁶⁷

Reasoning, they suggest, enables people to ‘produce arguments to convince addressees who would not accept what they say on trust’ – one consequence of which must be that in any society large enough that people no longer know one another well it becomes the default mode of discourse. Boxes have to be ticked, algorithms followed. Mercier and Sperber point to the fact that ‘when we reason, we know that we are reasoning, whereas the very existence of intuitive inference was seen as controversial in philosophy before its discovery in cognitive science’; and that ‘the very function of reasoning puts it on display in human communication’. In other words, it is rhetorically more appealing than any alternative – often, I would add, quite rightly, while accepting that if not tempered by intuition, it may lead to poor outcomes. Daniel Kahneman’s highly enjoyable *Thinking, Fast and Slow* brought into the popular realm ingenious work that he and Amos Tversky had been carrying out and publishing for about 40 years, demonstrating errors in reasoning.⁶⁸ In a discussion of Kahneman’s influential positing of system 1 (immediate) and system 2 (deliberative) thinking styles, Mercier and Sperber write:

It is sometimes claimed ... that the meliorative function of system 2 reasoning is achieved by correcting mistakes in system 1 intuitions. However, reasoning itself is a potential source of new mistakes. Moreover, there is considerable evidence that, when reasoning is applied to the conclusions of intuitive inference, it tends to rationalize them rather than to correct them.⁶⁹

We need to regain some middle ground here. Contemporary discourse can be excessively dismissive of intuition and feeling *and* of reasonable argument – hyperrationalistic and overheated at the same time (both characteristic of the left hemisphere). We should never dismiss reason, but then we should never just dismiss intuition, either. We need them to work together, since reason guided by intuition is better than reason that disregards it; and intuition that is not dismissive of reason is better than intuition that is. We need as many ways of getting hold of reality as we can. This is well put by Jonas Salk the discoverer of the polio ‘vaccine’. He suggests precisely the $R \rightarrow L \rightarrow R$ progression whereby the hemispheres work well together:

Reason alone will not serve. Intuition alone can be improved by reason, but reason alone without intuition can easily lead the wrong way. They both are necessary. The way I like to put it is that when I have an intuition about something, I send it over to the reason department. Then after I've checked it out in the reason department, I send it back to the intuition department to make sure that it's still all right.⁷⁰

For Salk, while intuitions should always be passed before the eye of reason, it is intuition that should always be the final judge. Bergson explains why:

... philosophers, in spite of their apparent divergencies, agree in distinguishing two profoundly different ways of knowing a thing. The first implies that we move round the object; the second that we enter into it. The first depends on the point of view at which we are placed and on the symbols by which we express ourselves. The second neither depends on a point of view nor relies on any symbol. The first kind of knowledge may be said to stop at the *relative*; the second, in those cases where it is possible, to attain the *absolute*.⁷¹

Intuition is not just another tool, like analysis: it inhabits, rather than inspects, the matter at hand:

By intuition is meant the kind of *intellectual sympathy* by which one places oneself within an object in order to coincide with what is unique in it and consequently inexpressible. Analysis, on the contrary, is the operation which reduces the object to elements already known, that is, to elements common both to it and other objects. To analyse, therefore, is to express a thing as a function of something other than itself. All analysis is thus a translation, a development into symbols, a representation taken from successive points of view from which we note as many resemblances as possible between the new object which we are studying and others which we believe we know already.⁷²

This distinction becomes of overwhelming importance when we try to approach inexpressible, because *sui generis*, experiences, such as those of time, space, consciousness and the sacred, as we will see in Part III.

FURTHER DECLINE IN THE FORTUNES OF INTUITION

None of the evidence of the importance of intuition has stopped its routine and often casual denigration. It seems that we have constantly to be told how unreliable our intuitions supposedly are – even when the evidence adduced to prove it often tends, on closer inspection, to do nothing of the sort. An important element is that adopting the apparently ‘sceptical’ posture puts the instant ‘expert’ in a one-up position compared with the poor old ‘man on the Clapham omnibus’, who appears naïve. Intuition is also a threat to a world-picture based on administration, adherence to ordained procedures, the power of technology, and a belief in the superiority of abstract mentation over embodied being. And to the reductionist, the power of intuition is also a threat that must be ‘debunked’.

A typical case happens to come to my notice as I write. A piece of research has just shown that confidence in your intuitions is only weakly predictive of whether they are good or not: ‘while confidence in one’s intuitions vis-à-vis a particular task at hand may bear some relation to actual intuition performance, the predictive validity is likely low.’⁷³ Notice two things. First, and relatively trivially, the research doesn’t show that if you think you are good at intuition you are *not*, just that if you don’t think you are, you still may be – if you are confident, you are not necessarily any more correct than someone with lower confidence in their judgment. Second, and much more importantly, it has nothing to say about whether intuitions are themselves valid – only about whether the strength of one’s belief that one’s own intuitions are valid is valid. As it happens, intuitions themselves are more often valid than not, as one of the authors of the paper himself states: ‘overall, actually, our intuitions are quite good.’⁷⁴ Yet how was this research reported on the web (by an author of ‘several health-related books’)? ‘Think your intuition helps you make wiser decisions? Probably not, say researchers ... A recent study from Great Britain suggests that relying on intuition may be yet another delusion we have about ourselves.’⁷⁵ The only deluded person here is the journalist.

Casual knocking of intuition matters more, however, when it appears to undermine faith in the way we make judgments, often with the implication that if only the human element could be removed, we’d all get along much

better. Earlier I described how, from my own experience, intuitive judgment plays a vital role in the practice of medicine, as it does in many other professions; and just how striking it can be. So in reading Kahneman's *Thinking, Fast and Slow*, I was struck by this passage, where he talks about medical expertise, and it gave me pause for thought:

Experienced radiologists who evaluate chest X-rays as 'normal' or 'abnormal' contradict themselves 20% of the time when they see the same picture on several occasions. A study of 101 independent auditors who were asked to evaluate the reliability of internal corporate audits revealed a similar degree of inconsistency. A review of 41 separate studies of the reliability of judgments made by auditors, pathologists, psychologists, organizational managers, and other professionals suggests that this level of inconsistency is typical, even when a case is re-evaluated within a few minutes. Unreliable judgments cannot be valid predictors of anything.⁷⁶

It wasn't the first time I had heard similar points of view expressed, but this struck me as remarkable for two reasons: it was unusually damning, and it didn't tally at all with my experience. Maybe I had been lucky to have had the honour to be trained exclusively by, and to work alongside, some particularly astute clinicians; but the idea that an experienced radiologist assessing a patient's chest X-ray would contradict himself or herself frequently, and sometimes after only a few minutes, was a bit of a surprise. So I decided to read for myself the source material on which this was based, which, of course, Kahneman scrupulously cites: he notes a paper in support of each of the first three sentences of this paragraph.

For the first sentence – 'Experienced radiologists who evaluate chest X-rays as "normal" or "abnormal" contradict themselves 20% of the time when they see the same picture on several occasions' – he cites a 1968 paper by Hoffman, Slovic and Rorer.⁷⁷

I looked it up. To my bemusement, I discovered that the paper had nothing to say about chest X-rays, or even about chests. It was about gastroenterology, and concerned not the interpretation of a single image, or indeed of a 'picture' of any kind. Nor did it concern a decision of 'normal' versus 'abnormal', but the far harder issue of whether in the abstract a

constellation of six factors on radiological examination suggested malignancy or not – not a cut and dried matter, and a question of balancing intrinsically uncertain signs, that are certainly abnormal, but may or may not mean cancer, often depending on the context, which here the ‘experts’ didn’t have. The test was highly artificial: assessing six pieces of ‘yes’ or ‘no’ data on a sheet of paper, as though one made clinical judgments outside the context of a specific patient, rather like solving a quadratic equation. Moreover, the radiologists in question were nine, three of whom were not even fully qualified, never mind experts; and of the other six their degree of experience is not reported – in which case it cannot be presumed that *any* of these clinicians were actually experts, for one very good reason, which James Shanteau explains:

In many studies, self-designation or scores on a short knowledge test are used to select ‘experts’. In other studies, job titles or academic credentials have been used. From the present view, such ‘experts’ in fact are more like novices ... Because of the exalted position of experts within their profession, it can be difficult for researchers to study or even to communicate with them. Experts typically are busy and reluctant to talk – and their time is valuable. In comparison, novices generally are more available and willing to talk – and their time is relatively cheap. It is therefore easier to study novices, but such research won’t answer questions about experts.⁷⁸

The one thing that was correct was that, in these rather different circumstances, the participants, whoever they may have been, were only 80% consistent. A machine of course would not have assessed two sets of criteria differently on two occasions. That, however, is not because a machine is superior, but because it is mindless and inflexible. A human being thinks, and therefore considers a range of possibilities where it may be artificial to suppose that just one of them is right. There may be good reasons to arrive at a range of conclusions, which human thinking better reflects.

I thought I might have better luck with the second paper Kahneman mentions. This is the one on which he bases the remark: ‘A study of 101 independent auditors who were asked to evaluate the reliability of internal corporate audits revealed a similar degree of inconsistency.’ I’m clearly no

expert on accounting, so, like Kahneman (I presume), I have to take what the author of the paper tells me – in this case, Paul R Brown, a distinguished professor of accounting, whose paper was published in 1983.⁷⁹

This concerned 288 questions of judgment – rating ‘satisfactory’, ‘adequate’, etc. More than half of the 101 subjects had between three and seven years’ experience: whether that makes them experts is also a question of judgment. Be that as it may, Brown writes: ‘Judgment stability averaged .79, which *indicated that the auditors were stable in their judgments.*’ In fact, about 80% stable. Or as Kahneman, neatly re-framing, would put it, ‘contradict[ed] themselves 20% of the time.’

Brown notes that, though ‘the current task was complex and not previously studied’, this complexity did not affect the auditors’ abilities to make consistent assessments, ‘which’, he reflects, ‘has been *a general conclusion of auditor judgment studies.*’ The analysis of their consistency in making decisions, he points out, required them always to make the same bald ‘yes’ or ‘no’ judgment on a matter in which such sharply delineated boundaries do not exist. Here, nonetheless, in a difficult area which involves problematic, cut and dried, responses on imprecise matters, they were impressively consistent. They were 100% consistent across all the judgments 80% of the time: if, under these circumstances, they had been more consistent, one might have thought they were accounting machines. Particularly note that this study confirms that it is in line with other auditor judgment studies.

So with some unease, and a growing fascination, I turned to the third of Kahneman’s papers, one by James Shanteau on expertise across a number of fields, and which therefore promised to be the most revealing.⁸⁰ To remind you, this was the ‘review of 41 separate studies of the reliability of judgments made by auditors, pathologists, psychologists, organizational managers, and other professionals [which] suggests that this level of inconsistency is typical, even when a case is re-evaluated within a few minutes.’ Shanteau, whose special area of expertise is experts, and who has studied experts for decades, had at this stage (1988) been looking at the question of expert judgment for the previous 10–15 years. He had originally, he tells us, come to the area with a bias against expertise, but ‘surprisingly’ discovered that the experts he looked at

were observed to be careful, skilled, and knowledgeable decision makers ... Since then, my emphasis has been on investigating factors which lead to competence in experts, as opposed to the previous emphasis on incompetence.

There is no mention of '41 separate studies' of the reliability of judgment, which the naïve reader was entitled to expect. However, there are 46 papers listed. Nine of the papers are critical of experts. 37 are either neutral or supportive of experts. Shanteau makes no reference to 'a few minutes', so that must be an embellishment by Kahneman. However, what he does say is:

Current expert systems typically take much of the communication and confidence away from decision makers. Such systems, in effect, alienate the expert from his/her normal psychological environment. It should not be surprising, therefore, to find that decision makers are unwilling to work with systems which are fundamentally incompatible with their perceived roles as experts. If this analysis is correct, then more attention should be directed to preserving the role of the decision maker in expert systems. That is, *systems should be designed about the needs of the experts, rather than expecting experts to adapt to the needs of the system.*

This is directly relevant to the role of experts today.

Kahneman's last sentence is also worth noting: 'Unreliable judgments cannot be valid predictors of anything.' Well, yes – but that seems a bit like loading the dice. Most expert judgments are not predictions, but assessments or diagnoses. Prediction is another matter, and very difficult – especially about the future, as Niels Bohr is said to have said. We all make projections: it's a necessary part of life. But it's wise not to do it any more than you have to, and to admit your uncertainty. Whitehead was a bit fiercer:

The world's experience of professed seers has on the whole been very unfortunate. In the main, they are a shady lot with a bad reputation ... On the whole, the odds are so heavily against any

particular prophet that, apart from some method of testing, perhaps it is safer to stone them, in some merciful way.⁸¹

Not all, or even many, expert judgments make predictions. Though expert judgments cannot always be correct, they are definitely not so uncertain as to be worthless – even as a basis for prediction, which mainly they do not pretend to be. One reason that experts in economics and politics are so often ridiculed is that their role makes prediction almost inevitable, and it can turn out to be disastrously wrong. It should not be forgotten, however, that their judgment is not in *opposition* to that of computerised algorithms, but, as in the disastrous failure to predict the financial crisis of 2008, reliant on sophisticated theoretical models *operated by* computer algorithms. But then, why have a superstitious reverence for computers? They are only an externalisation of an extreme form of one kind of human thinking, not known for its wisdom, and dependent entirely on the human mind that gave them their instructions. George Soros does better attending to sensations in his back.⁸²

And, if you want an example of successful prediction, the judgment of Franck Mourier is about as non-analytical as it gets, and as typical of the embodied skill of an expert as you could want; the accuracy of his predictions is clearly demonstrated by the very good living he makes from them.

Most expertise, to the extent that it involves prediction at all, is about choosing the right *next* move, not the ultimate outcome. A wise physician can advise on the next step of treatment, but can't tell you when, or of what precisely, you will die. A chess Grandmaster can see the best next move, but not usually how the game will end. A military strategist can see what needs to be done now, but not, with any degree of certainty, what will happen at a later stage – and would consider it foolish to think that you could.

Most tests of expertise are, in the nature of things, highly artificial. One recent study of physicians is typical. It found that 'although expert physicians outperform all other groups [at medical diagnosis], their accuracy is far below the maximum score.'⁸³ Well, there's a surprise – on both counts. And the finding needs to be contextualised. The study involved the diagnostic process relating to four patients' case histories, each containing about a hundred pieces of information, abstracted from notes and

anonymised: any information that was thought to make the diagnosis too easy for an expert was deliberately withheld. It is well known that experienced doctors – in fact, in proportion to their experience – make extensive use of contextual information, such as how the patient looks and comes across (rather like Franck’s intuition about horses), so that a decontextualised case, especially one in which vital information has been withheld, is not a good model of what doctors do.⁸⁴

What’s more, only half the cases lay within any one expert’s field (eight pulmonary physicians and eight cardiologists). One of the findings of the study, which should hardly surprise anyone, was that medical experts construct a representation of a clinical case much more rapidly and more accurately than those who are not experts. Oddly, the authors confess to having no idea why this would be the case.

Meanwhile, the ‘maximum score’ would involve making maximally detailed and accurate diagnoses on all cases, inside and outside your speciality. For example, for a correct diagnosis of carcinoma of the lung you would get only 3/6: to get 6/6 you would have to have ‘small cell lung cancer with metastases in the mediastinal lymph nodes’. Given that cardinal signs of the condition – such as weight loss – were omitted, and given that clinicians approach diagnosis from a view of the whole patient, precisely *not*, as the learner does, from a mass of data, it is surely not a poor outcome that more than 15% of the pulmonary experts and more than 6% of the cardiologists nonetheless achieved a perfect 6/6 in *every* case, within and without their expert area, merely from abstract scripts.

Not only do experts need a lot of experience, so as to have enough patterns to match, and so as to know how much weight to attach to each, they also need to be acting intuitively if they are to display the effects of their expertise. Experts acting intuitively are clearly better than *non*-experts acting intuitively, as might be assumed; but, importantly, they are also clearly better than experts who are making systematic, operationalised judgments – which is how one is forced to proceed in studies of the kind just described, and increasingly in day-to-day practice in the ‘enlightened’ bureaucracy that is Western medicine in the twenty-first century.⁸⁵

That experts don’t know how they do what they do is evident, from the confabulations, and *post hoc* rationalisations, that they proffer when asked – if they can find anything to say at all. When the articulate left hemisphere

knows nothing about what is going on elsewhere in the brain, it makes up plausible theories, which happen to be entirely false.

RULES OF THUMB

Another cause of mistrust in intuition is another of Kahneman's targets: heuristics – effectively, rules of thumb. These are assumptions made on the basis of what usually seems to be the case in similar circumstances, and are not infallible – eg, that when you have a headache it is caused by tension, not a tumour. The majority of the time, like prejudices, they will be accurate, so they are far from useless. Indeed, we couldn't possibly get by without them.

I am also including here what are known as cognitive biases. They are different, in that the rule of thumb, while generally serviceable, works well, but not in every situation; while cognitive biases are always distortions. An example is 'framing' – in other words, the way in which the same information is presented influences how we decide. Thus, a classic case from Kahneman and Tversky goes like this. Subjects are asked to imagine preparing for the outbreak of a disease which is expected to kill 600 people. They are divided into two groups. Each group can choose one of two regimes to combat the disease. One group is told that the options are a regime whereby 200 people will be saved, or one in which there is a 1/3 probability that 600 people will be saved, and a 2/3 probability that no people will be saved. Under these circumstances, 72 % of participants preferred the first regime, only 28% the second. The other group is told that the options are a programme whereby 400 people will die, and one in which there is a 1/3 probability that nobody will die, and a 2/3 probability that 600 people will die. In this situation, 78% preferred the second programme, only 22% opting for the first. The problem is that these choices are effectively the same.⁸⁶

As a psychiatrist, I am only too well aware how many cognitive errors lie in wait for the unwary. Rarely are these actually a matter of 'intuitions', more of fixed ideas or beliefs (a left hemisphere speciality). It seems to me that some sorts of cognitive trap are so widespread and lead to such misery that we should be taught about them in school. I am thinking here of those distortions that the process of cognitive therapy helps to illuminate (and, with luck, almost eliminate), and which are applicable in almost anyone's

thinking: if you think they don't apply to you, congratulations – your bias blind spot is working well. These include:

- *selective abstraction*

dwelling on the small thing that went wrong, not the whole that went well:

'I overcooked the beans, so the whole evening was a failure'

- *arbitrary inference*

jumping to conclusions on no evidence:

'I just know from her tone of voice that she thinks I am fat'

- *minimisation*

inventing grounds to dismiss your successes:

'OK, I got good grades, but that was a fluke – probably someone else's papers'

- *magnification*

exaggerating one's shortcomings:

'I forgot her birthday – what a selfish bastard I am'

- *personalisation*

exaggerating one's part in the responses of others:

(awaiting a reply to a long letter): 'I must have offended him – what did I say?'

- *dichotomous thinking*

taking black and white, all or nothing views:

‘Either it’s perfect, or it’s worthless’.

Usually a moment’s reflection shows how unreasonable they are.

But the sort of cognitive biases that I am writing about in this chapter are less global, less emotional, less a failure to observe the evidence. They are more local, more purely cognitive, more clearly failures of the reasoning process itself. The thrust of *Thinking, Fast and Slow* is that in many situations we make quick and dirty decisions which are inferior to those we would take if we thought more carefully and took our time. Kahneman also points out that we need both approaches, since having a repertoire of more or less automatic responses that tend to work most of the time is necessary for survival, life often presenting us with situations that afford no time for reflection. He therefore constructs a two-system model, ‘system 1’ being quick and dirty (unreliable), and ‘system 2’ slower, more deliberative (reliable).

Thus, for example, you have bought a ticket to a football match. On the day, it is wet and you feel unwell. Getting there requires three changes of public transport and a walk. It would be much more enjoyable to stay at home and watch it on TV. But you don’t: you don waterproofs and go – because, after all, you have paid £75 for the ticket.

But you’ve paid that anyway. You can either have paid £75 and be comfortable, or have paid £75 and be miserable. Apparently the thought of having unnecessarily paid £75, which can’t now be undone, weighs more heavily than anything else, and leads to us making a bad decision. (By the way, we are often swayed by such considerations: that we should not waste is a stronger consideration with some than that we should eat only what we need and want – and indeed it is not entirely irrational.)

Then there are some strictly logical mistakes. One that is interesting for what it reveals about the way we think is the so-called Wason test, one of the most famous in cognitive psychology

(see Plate 16[c]). Most people do not get this right on the first attempt. Try it for yourself before reading on.

The correct answer is: you need to turn over the 8 and the brown card. Whatever is on the other side of the red card doesn’t matter, since the claim is not about what is on the other side of a red card, but what is on the other side of an *even* card. So if the brown card should turn out even, it violates the rule (as would the 8 if it turned out brown).⁸⁷

However, if the test is set in a social context, most people get it right (see Plate 16[d]).⁸⁸ This test has exactly the same logical structure as the earlier one, but is much easier to solve.

Yes, it's the 16 and the beer-mug. It is argued that this is easier because we reason better in circumstances that have human meaning – which is probably why we teach children not just to take two from five, but to imagine Mary having five apples, giving two to Bob, and then seeing how many Mary still has.

There is an interesting rider to this, from a social point of view, which is that when groups attempt the problem in its original form, they do very much better than single subjects. In studies, only 9% of the individuals made the right selection on their own, by contrast with 75% of the groups. And the superior performance of the groups was due to collaboration, rather than to imitation or peer pressure.⁸⁹ This sounds like unexpected good news. As another paper from the same field puts it:

This 'Truth Wins' scenario is in total contrast to what psychologists will normally tell you about group function. In most domains, from creativity to tug-of-war, a phenomenon called 'social loafing' holds, whereby the performance of the group is less than the sum of expected effect of individuals acting alone ... The groups in these experiments have a common goal, and – we must assume – trust each other and are committed to the task. Furthermore the solutions can be demonstrated to be correct. In these circumstances rational argument is productive.⁹⁰

However wrong our quick and dirty assumptions may be occasionally, there may, in general, be more to be said for them than we are allowed to think. Heuristics are highly adaptive and all living creatures employ them in some form. Ant colonies, for example, send out 'scouts' in search of a potential nest – say, a narrow crack in a rock. Such a scout has to estimate whether the area is big enough to house the colony. Not having a tape measure and a slide rule, it does this by using a heuristic. It runs around randomly, leaving pheromone trails of a certain length, then leaves. After a period, it returns, this time moving on a different random path. By noting the frequency with which it encounters the old trail, it can estimate the size

of the cavity. The heuristic is remarkably accurate: in a laboratory experiment, a 'nest' of half the area produced almost exactly twice (1.96 times) as many encounters.⁹¹

It is obvious that heuristics are universal because they are generally on target. They are not, as now seems widely to be believed, the product of a flawed mental system.

Most problems of interest in the real world are intractable to computation. That is why artificial intelligence researchers and engineers often rely on heuristics to make computers smart. However, according to Gigerenzer, who is the Director of the Max Planck Institute for Human Development in Berlin, in the 1960s and '70s the term heuristic acquired a different meaning. No longer regarded as a way to make computers seem smart, it became a way of making people seem dumb. Statistical tools run by computers became the models of cognition, with the consequence that human thinking became viewed as a weak approximation to statistical procedures.⁹² Heuristics were now viewed as preventing one from finding out or discovering correct answers to problems assumed to be in the domain of probability theory – poor substitutes for computations that are too demanding for ordinary minds to carry out.

Although in the literature it was repeatedly emphasised that heuristics are sometimes good and sometimes bad, by an odd coincidence virtually every experiment was designed to show that people violate laws of logic, or probability, or some other standard of rationality. Thus there arose, Gigerenzer continues, widespread misconceptions that heuristics are always second best, that we use heuristics only because of our cognitive limitations, and that more information, more time, and more computation (which computers ought to make possible), would always be better.

In many situations, it's not just that finding the optimal result – assuming, and it is a big assumption, that there is such a thing to find – would be time-consuming. It's that it is intrinsically impossible, either because we do not have, and can never have, enough data, or because the goals defy simple definition. Heuristics are indispensable for good decisions in uncertain situations, which is what life mainly offers. In an uncertain world, good decisions require ignoring part of the available information. The more noise in the observations, the more likely a simple heuristic will outperform more flexible strategies.⁹³ Complex problems do not always require complex solutions.⁹⁴

In a situation where there is low uncertainty, few alternatives to choose between, and a lot of good quality data to go on – sure, adopt a computational model. However, in the considerably more likely circumstances that there is a good deal of uncertainty, there are many alternatives, and relatively few reliable data (small sample sizes relative to the number of factors involved and their possible interdependence), you would be wise to adopt a heuristic. Even ‘one reason’ decision-making can, under certain circumstances, be more effective than analyses that use more information – and those circumstances tend to be common in the world outside the lab.⁹⁵ Sometimes less information and computation can actually lead to higher accuracy.

Note it’s not that, in these situations, we make a trade-off of accuracy against effort. A ‘less is more’ effect holds: the mind would not gain anything from relying on complex strategies, *even if* the costs (including opportunity costs) of such strategies were zero – which, of course, they never can be.

Nonetheless, Gigerenzer developed the concept of the ‘ecologically rational’ heuristic, by which he meant the selection of the right heuristic for the context, so as to make accurate inferences in a ‘fast and frugal’ way. Thus the rationality of a particular decision depends not just on its *internal* logical structure, but on its selection for the *circumstances* in which it takes place. What is considered rational under the ‘rational choice’ account thus might not be considered rational under the ‘ecological rationality’ account, and vice versa. This is reminiscent of, and possibly formed by analogy with the psychologist Egon Brunswik’s idea of ‘ecological validity’, namely that an organism cannot be considered separate from its environment. That environment is always uncertain, and adaptation to an uncertain world requires learning to employ uncertain evidence. As before, precision can be inaccurate.

The attempt to find the optimal result itself leads to errors. Because of this we rely on heuristics not just in routine decisions of little importance, but – and perhaps especially – in those of great significance, such as where to live, whom to marry, and how to invest. It is also a mistake to imagine that clever people don’t use heuristics. Intelligence seems to manifest itself in the choice of heuristic, rather than in abandoning them altogether in favour of some less efficient form of decision-making.⁹⁶

A nice example concerns Harry Markowitz, who received the Nobel Prize in economics for finding the investment strategy that produces maximum return for a specified level of risk, called mean-variance analysis. Its general expression is contained in these formulae:

$$E(R_p) = \sum_i w_i E(R_i)$$

$$\sigma_p^2 = \sum_i w_i^2 \sigma_i^2 + \sum_i \sum_{j \neq i} w_i w_j \sigma_i \sigma_j \rho_{ij}$$

However, when he made his own retirement investments, he did not use this strategy. Instead he relied on a traditional rule of thumb known as naïve diversification. This means dividing the investment equally between a small number of funds and hoping for the best. This strategy was first proposed by a fourth-century Rabbi, Issac bar Aha; fund managers not having been invented, the aptly named Rabbi Aha recommended having a third of your wealth in property, a third in merchandise and a third in cash.⁹⁷ Of course, he didn't win a Nobel Prize, but according to some measures his method apparently outflanks every subsequent complex strategy.⁹⁸

It is not always rational to act according to the dictates of logic:

Behavior is often called rational if and only if it follows the laws of logic or probability theory, and psychological research has consequently interpreted judgments that deviate from these laws as reasoning fallacies. From a Darwinian perspective, however, the goal of an organism is not to follow logic, but to pursue objectives in its environment, such as establishing alliances, finding a mate, and protecting offspring. Logic may or may not be of help.⁹⁹

For instance, in any series of Prisoner's Dilemma games, two supposedly 'irrational' players, using the heuristic 'tit for tat', fare better than do two rational players who cannot escape the conclusion that the

logical thing has to be to defect.¹⁰⁰ Tit for tat is a shorthand for the reciprocity that helps cement a stable society. And others, like the ‘recognition heuristic’, help us keep track of complex patterns of information in a continually changing world.

Even cognitive distortions, such as the so-called ‘framing’ effect, are the price we pay for seeing things in context; if we did not, as a rule, we would be much more deluded than we are. If you have to choose a quick route you will take the one that *in all probability* works best, not necessarily the best one on this occasion. You just can’t, usually, have it all ways. Having to reason everything out is as disastrous as never doing so at all: the upshot is that we need to know when to do what. And there isn’t a formula for that.

Our choices rarely follow a calculus, which makes us look more irrational than we are. For example, not jumping in to save a life when you could have is equivalent, on a consequentialist calculus, to killing – even jumping in and ducking someone under till they drowned – since both result in a death that could have been obviated had you acted otherwise; but a person who could not see the difference would surely have to be severely functionally autistic. And presented by a psychologist in a test situation with choices involving risk, an experienced person is more likely to focus narrowly on what is stated as certain, because things that are probabilistic only, or implied only, carry less weight when we are not taking a decision in a situation of trust – a sensible heuristic itself, which applies in the ‘treatment regime’ example mentioned earlier. How we respond depends on a whole raft of incidental factors that are hard to control for. We would expect people to take less risky-sounding options as they get more experience of life, and that is indeed the case:

Mature adults apparently resist taking risks not out of any conscious deliberation or choice, but because they intuitively grasp the gists of risky situations, retrieve appropriate risk-avoidant values, and never proceed down the slippery slope of actually contemplating trade-offs between risks and benefits. ¹⁰¹

This is in part because what is called *qualitative* reasoning – human reasoning, in effect, which takes into account such matters as relevancy of factors, factors that can’t be quantified, elements that are ambiguous, and so

on – increases with age. Very young children are more likely to make decisions based on quantitative properties only. The use of heuristics markedly increases in line with cognitive capacity during child development.¹⁰²

This not to say that we don't make egregious errors through unconscious cognitive biases: they are important to understand. One of the most comical examples is that people given a heavier clipboard to hold papers judged the matter to which the papers referred to be 'weightier' than those who were given a light one.¹⁰³ On the other hand, holding in your hand a document that is supported by more information and in which arguments are more thoroughly explored will usually mean more weight of paper, so it's not *quite* as daft as it seems. And subjects carrying a weight on their backs judge an incline to be steeper than those who are not similarly encumbered¹⁰⁴ – but we naturally interpret circumstances in an embodied way: a hill is an invitation to climb (perhaps especially when we are primed by carrying a backpack), and our bodies sensibly register the effort we are invited to make. Highly artificial circumstances produce highly artificial results.

In a certain test, subjects are invited to read the following display (in which the word 'the' is repeated),

Fig. 36. The effect of expectation on perception

John Kay writes, of those who miss the repetition:

This is a mistake – or so the experimenter thinks. But who is really making the mistake: the pedant who offers the direct answer and reads 'a bird in the the hand'? Or the person with a life, who

approaches the problem obliquely and valiantly finds sense in nonsense?¹⁰⁵

This has its parallel with visual illusions. Visual illusions are in fact short cuts that come with experience, and involve seeing the context. Hence the chequerboard illusion at the outset of this chapter. And appreciation of context comes not from theory but from experience. The left hemisphere does not have it. There is an illusion known as the Ebbinghaus illusion in which context alters our perception (see Plate 16[e]: in children, susceptibility to the Ebbinghaus illusion is rarely present before 6 years old.¹⁰⁶

In schizophrenic subjects, who have many right hemisphere-typical deficits, reduced sensitivity to the illusion is related to an increase in what are called ‘disorganised’ (effectively, bizarre) symptoms;¹⁰⁷ more normal performance (being ‘deceived’ by the illusion) is related to a higher level of *depressive* symptoms – which are associated with the right hemisphere.

And we shouldn’t feel bad about the fact that scents shape our impressions of a person or a situation; millions of years’ worth of information from experience is encoded in scent. That unscrupulous people can use scents to alter our shopping behaviour is hardly different from any other form of deceit. In one study carried out at a clothing store, the scent of vanilla doubled the sales of women’s clothes.¹⁰⁸ And so? Supermarkets use lighting that makes the colours of tired vegetables look more vibrant. We don’t assume *we’re* at fault somehow.

There are many more reasons we behave ‘irrationally’, and they are too numerous, and too well reviewed elsewhere, for me to need to go into them all here. The interested reader will find most of them beautifully covered in Kahneman’s book. But there are two main things to say about them.¹⁰⁹

One I have addressed already: it is easy to run away with the idea that all occasions on which we can be deceived are a proof that we are hopelessly fallible, and our brains are an inferior sort of machine. Those entertaining studies bulk large in social psychology research because this is what social psychologists enjoy studying. It is also, in an era of mass media, what big business, advertising and government propagandists want to know about, for obvious and unwelcome reasons, which makes it a fashionable and lucrative area of research. In reality, while they are assuredly not

insignificant, they are the intermittent downside associated with our being able to do far more than a machine can, or will ever be able to do, until it has blood coursing through its chips. To be wholly rationalistic, and incapable of knowing how to blend logic with all that emotional, social and embodied intelligence tells us, would spell disaster for a human being, as the rare cases where, by some unhappy accident of nature, someone comes even near to such a condition confirm. You will remember Damasio's patient 'Elliot'. But since, unlike logic, such social and emotional intelligence is simply not open to quantification, the downside of it is that at times, inevitably, we appear to 'miscalculate'.

The other is that I am not sure how strong a case can be made for calling such miscalculations 'intuitions', rather than cognitive errors. I have included them here because they are often attributed to intuition. But not reasoning correctly does not, of itself, imply intuition at work. Indeed, it is claimed by some psychologists and philosophers of choice theory that the association between heuristics and intuition is 'unwarranted'.¹¹⁰ Essentially, it is argued, we make almost all decisions in life unconsciously, using a holistic, parallel processing system that is aimed at producing the highest level of consistency between an array of possible elements. Unlike the picture we get when we try to reconstruct after the event what went on, we do not at any point have fixed elements that have to be then weighted, and combined according to 'rational' rules – *whether accurately or fallaciously*. Instead, the system is unconscious, ceaselessly dynamic and recursive, making attempts to recontextualise what information we have so as to make it cohere, and as each element shifts because of its new position in this network, the other elements too must shift however slightly, until a system of optimal integration is achieved.

It has been possible repeatedly to distinguish experimentally between reliance on heuristics, which are sequential and rule-based, and reliance on parallel, holistic but compensatory modes of decision-making, which are taken to characterise the intuitive mode.¹¹¹ And studies have reported that errors resulting from framing effects (as in the disease problem, above) actually increase, rather than decrease (as the traditional view would have predicted) with the requirement to deliberate.¹¹² Another case where less is more.

Evidence suggests that things are likely to be more complex than Kahneman's two-system model suggests. Contrary to his assumption,

reasoning based on beliefs, assumed to be automatic, can, it turns out, be effortful; while reasoning on the logical structure of an argument can be accomplished fairly automatically.¹¹³ ‘Given this analysis’, ask Simon Handley and colleagues, ‘why is it so commonly assumed that belief-based reasoning is automatic and logical reasoning effortful?’ They set out to test this assumption and found that

certain logical inferences are accomplished relatively automatically and are immune to the influence of beliefs. In contrast, judging the believability of a conclusion appears to be a slower process that can be readily interfered with and inhibited by logical analysis. This pattern is exactly the opposite of what would be expected if belief-based judgments were based on fast, automatic, Type 1 processes and logic-based judgments were based on slow, deliberate, Type 2 processes ... At the very least the present findings suggest that it is overly simplistic to associate beliefs with default responses and judgments of logical validity with effortful cognition. The reality is much more complex and suggests a major re-evaluation of dual-process theories of reasoning and judgment is required. ¹¹⁴

In line with a series of recent studies,¹¹⁵ they found that a certain degree of logicity must in fact be achieved through intuitive processing: ‘This result paints a rosier picture than what we could infer from all the investigations of the pitfalls of human rationality ... Our findings present intuitions and logical reasoning not as two competing forces (which usually act in opposition) but as two complementary sources of human rationality.’¹¹⁶ A conclusion with which I would strongly agree.¹¹⁷

The Harvard and Oxford philosopher Hao Wang has something to say on this that both helps bring together the ideas of intuition and analysis, and to some degree exonerates philosophers from the indictment, with which we are familiar, that they already have their conclusions before they start. He holds that they might do so by intuition, but that philosophy is the somewhat blunt instrument with which they *quite rightly and necessarily* have to justify their position, given the world view of their interlocutors – namely, ourselves:

A familiar experience in mathematics is that one is often convinced of the truth of a proposition or something close to it but cannot quite prove it or gets only a defective proof. A good and experienced mathematician seldom errs far in such situations because intuition seems to be *a less exact but more dependable* guide than a formally exact proof, just as the human brain can tolerate more error and indefiniteness than a computer. More generally, we often have perfectly reasonable beliefs but cannot give good reasons for the beliefs ... I agree that we should try hard to see whether our deeply held beliefs can be disproved, especially when we make crucial decisions on the basis of such beliefs. But for me a more fruitful approach to philosophy than systematic doubt would seem to be to search for reasons to support our basic beliefs, which may be somewhat indefinite ... ¹¹⁸

And he goes on to give the example of Kant, whose philosophical development was a 'continued attempt to give a structure to his *Weltanschauung*, which remained pretty much invariant throughout Kant's changes in his doctrines'. He quotes the philosopher LW Beck:

By *Weltanschauung* I mean here: a set of philosophical ideas and opinions held together in a personal attitude, but without the benefit of the technical discipline of analysis and argumentation ... We find a high degree of likeness between conclusions reached in works written [by Kant] over five decades during which profound changes occurred in his premises and modes of argumentation. ¹¹⁹

Before we leave this section, what about the time course and hemisphere contributions?

The typical time course of heuristic thinking is instantaneous, or at any rate brief. That is its advantage. It is largely unreflective and usually involves 'snap' judgments. However, it may take years of experience for the foundations of those judgments to evolve to their established condition. In this it is analogous to prejudice.

In terms of the hemispheres, this is not a clear issue. Kahneman's system 1 and system 2 cut the cake 'horizontally' (top brain versus bottom

brain), whereas I am cutting it ‘vertically’ (left versus right). His systems 1 and 2 don’t map onto left and right hemispheres, but rather slice the brain at right angles to the interhemispheric fissure: both hemispheres are involved in heuristics, and both in deliberation, a point on which Kahneman agrees, though he does not deal with hemispheric differences in his book.¹²⁰ As far as ‘fast’ and ‘slow’ thinking goes, jumping to conclusions (LH) is fast, but so is flawless intuition, as in the case of Franck Mourier (RH); following algorithms is slow (LH), but so, at least relatively speaking, is acting as devil’s advocate (RH).

However, as I have already suggested, it is the left hemisphere that is considerably more prone to settle for its heuristics, the right hemisphere more inclined to be cautious. When urgent, target-oriented action is even contemplated, this activates the left hemisphere. So the left hemisphere is prone both to make swift judgments and to stick to them unreasonably.

And as if to emphasise the point about speed, time pressure impairs the all-important re-balancing activity of the right lateral prefrontal cortex: deliberative rationality – Salk’s third stage – not calculative rationality.¹²¹ So what Kahneman is pointing to seems to be that when we are not given sufficient time for reasoning, we rely on the ‘fast heuristic system’ (the quick and dirty approach, to you and me), which both hemispheres subserve, but the left hemisphere more extensively. If the heuristic is a good fit, which it often is, this is fine; if not, it leads to entrenchment of bias.

THE PERILS OF MISTRUSTING INTUITION

Intuitions are a kind of feeling, we say – which is probably little more than an acknowledgment that they are not examples of explicit thinking. But if they were to partake of the nature of feelings, would that be to discount them? Reason is not opposed to feeling, but dependent on it. ‘There is no such thing in practice as a desire without a belief or a belief without a desire’, writes philosopher Robert Ellis:

We need to start seeing alienated boffins not as ‘unemotional’ but as people with over-abstracted metaphysical beliefs that interfere with their emotional integration. Similarly, an ‘emotional’ person has lots of beliefs which they are reasoning about a good deal: just on the basis of over-narrow assumptions. It is this false dichotomy between rationality and emotion that, I think, more than anything, is responsible for moral failures in the history of Western thought.¹²²

Hume would have agreed. ‘By reason we mean affections’, he wrote, ‘... but such as operate more calmly, and cause no disorder in the temper: which tranquility leads us into a mistake concerning them, and causes us to regard them as conclusions only of our intellectual faculties.’¹²³ As CS Peirce puts it, ‘Man is endowed with a form of emotional rationality; he has the ability to cognize from his disposition to feel; what is valuable seems to be immediately felt and cognized.’¹²⁴ Remember that Peirce was a logician and mathematician. Any dichotomy is too harsh: even the impulse towards a certain kind of logic suggests an emotional reaction to the intersubjective experience of the world, even if the primary emotion is sometimes negative. It is feeling that taught mankind to reason, as Vauvenargues observed during what is often called the Age of Reason.¹²⁵ An irrational fear of emotion leaves us cognitively impaired.

There is a difference between the irrational – something that is defined by its opposition to reason – and that which transcends, reaches beyond, rationality, where rationality no longer can hold sway. This is not to exalt the irrational, but to pay due respect to what one might call the ‘supra-

rational'. In this realm lies intuition, and by one's openness to it no claim is made that it is somehow infallible.

Intuitions can change with time and place, rather as moral codes do: yet neither should be thought of as for that reason random, or as something entirely invented, rather than in part discovered through experience. To both intuitions and moral codes there is a remarkably consistent core over time and place, though much may change 'around the edges'. For the health of any society, one of the most important senses is that of the *reasonable*, one of the best examples of something that is clearly context-dependent, not just in its proper functioning, but in its constitution: a combination of rationality with intuitive understanding. The reasonable is enormously hard to reduce to rules or principles, yet without it we cannot function properly as a society: it is a vital concept in law, and ironically, since the law is often conceived to be about rules and principles, the law may be one of the last places left in which it is evident. But it should be, and largely was, evident in many other areas of life, where systems have now become mechanical, inflexible, black and white, entirely neglectful of context – in other words attuned to the computer, not to the human person. It is a worrying reality that we could lose our intuitive sense of what is reasonable altogether if it gets no reinforcement from day-to-day experience.

Intuitions are laid down in strata, like layers deposited on a river bed, precipitating slowly out of experience, and therefore shaping ongoing experience – but over time they can be washed away. When the water that flows in the river changes sufficiently in its rate of flow, or its composition, the river bed changes. And that water – our experience – is changing rapidly, as I have suggested, because we attend to the world differently; and from different attention comes, inevitably, different experience of the world.

But, like the river bed, intuitions have, as I suggest, layers. And the layers may differ in their nature. Thus it is possible to speak of our 'now intuitive' belief in the mechanistic world-picture, but this is a recent accretion on top of much older intuitions about the world as living, organic, responsive, whole – intuitions that I believe science may be in the process of validating once more.

Speaking of the intuitionist logic of the mathematician and philosopher LEJ Brouwer, Karl Gustafson, a professor of mathematics at Boulder, Colorado, writes:

I would like to ... assert, far beyond just mathematical logic, the same larger, richer value of intuition over formal reasoning as a general proposition in physical science and human affairs ... Just because we cannot codify our intuition does not mean that it does not exist. It may be inconsistent, but it may also be more complete. And as an accumulated underlying partially conscious, partially unconscious, experience and knowledge base, its overall intellectual value far exceeds any single rational deductive process that one may bring to bear on a scientific or human problem.^{[126](#)}

And yet we are intent on a process the aim of which is to banish intuition from all aspects of our lives. In doing so we drastically simplify what we inspect, and cut it off from the roots by which it lives. 'At all levels of society computer-type rationality is winning out', wrote Hubert and Stuart Dreyfus over 30 years ago:

Experts are an endangered species. If we fail to put logic machines in their proper place, as aids to human beings with expert intuition, then we shall end up servants supplying data to our competent machines. Should calculative rationality triumph, no one will notice that something is missing, but now, while we still know what expert judgment is, let us use that expert judgment to preserve it.^{[127](#)}

By now, it may be too late. Some people already seem to believe we are better off in the hands of our new masters, the machines. The fact that machines have been trained to make accurate assessments of, for example, skin lesions does nothing to weaken, but instead strengthens, the case that humans should not be discouraged from using intuition. What these machines have been given is a vast bank of already humanly diagnosed images and made to find measurements that correlate: the advantage of the machine is speed. It carries out a mechanistic procedure, but at prodigious speed. If humans behave mechanistically, they fail: intuition is faster and smarter. A constant insistence on dis-attending to intuitions and placing reliance instead on standard assessment forms and checklists replaces the unmeasurable but often astute assessment of a real human being with the bogus precision and lack of individual flexibility of a machine.

Analytic processes are helpful only when something has gone wrong, or because we are complete beginners. Philosophers and psychologists who have championed the view that our mental processes are akin to those of a computer seem not to notice that we become dependent on analysis only when things are not going smoothly or when someone performing an experiment has given us a task in which we have no prior experience or skill. ¹²⁸

‘To participate in the construction of a model’, according to Dreyfus and Dreyfus,

an expert must regress to seeing the world like an advanced beginner or, in some cases, a novice. If experts fail to appreciate the extent and importance of their unrationalised know-how, they may not realise how seriously their own understanding is being degraded; they may even be flattered into believing that the model constructed on the basis of their answers to the model builder’s questions captures and amplifies their expertise ... The increasingly bureaucratic nature of society is heightening the danger that in the future skill and expertise will be lost through over-reliance on rationality. ¹²⁹

Medical expertise is once again a fruitful example. ‘Doctors are among the most highly skilled of human experts’, the authors continue, ‘and we would expect that they would recognise the intuitive factors in their decision-making: they are, however,

tempted to rationalise their intuitive decisions not only to justify them to themselves and their peers, but also in order to explain them to their patients ... Yet there is a danger of overvaluing explicable forms of knowledge if the patient makes the ultimate decision regarding treatment, based on the facts furnished by the doctor ... In reality, a patient is viewed by the experienced doctor as a unique case and treated on the basis of intuitively perceived similarity with situations previously encountered. That kind of wisdom, unfortunately, cannot be shared and thereby made the basis of a patient’s rational decision ... To confuse the common sense, wisdom

and mature judgment of the expert with today's artificial intelligence, or to value them less highly, would be a genuine stupidity.¹³⁰

There is a complete misunderstanding of what it means to 'know' something nowadays. Thus grand claims are made by clever psychologists that we ordinary folk say we know how something works without 'really' *knowing* it at all.¹³¹ But different kinds of knowledge are here being confused. In relation to everyday matters, we know what we need to know in order to interact with an object. Thus if I say I know how a fridge works (in the sense that I know it is a heat exchanger that creates a cool environment for food), I am not suddenly revealed to be a charlatan just because I can't explain in detail, when asked, how heat exchange is accomplished. It's a matter of the level of appropriate detail. But it's also a matter of embodied versus verbally explicit knowledge. When I say I know how to tie a bow tie, my fingers can accomplish the task easily, but my tongue won't offer a satisfactory account. That is not a 'folksy' failure of the human mind: it is a triumph of the human mind over engagement with unnecessary detail and the proceduralisation of what is not naturally proceduralised. Do I know how I pick up a plate? Of course I do. The fact that I can't any longer give a detailed account of sliding filament theory (a mechanism that enables muscle contraction) doesn't have anything to do with it. This sort of thing knows no end. Is sliding filament theory enough? Or do I need to explain voltage-gated calcium channels in order to 'know'? If so, do I need to be able to distinguish between L-type, P-type, N-type, R-type and T-type calcium channels, in order to count as knowing how I move my arm? This way madness lies.

The historian Jerry Muller, in his devastating critique of contemporary managerial culture, in academia, in medicine and the other professions, *The Tyranny of Metrics*, makes many important points. One is the way in which making things explicitly measurable not only, as is very well known, distorts the practice that is being measured, focussing attention, both for the professional and for the bureaucrat, on what is measurable at the expense of the important elements that are not, but how it narrows our sense of what we are dealing with – confirming the point that an intuitive understanding takes into account far *more*, not less, than the management measures. 'Quantification', writes Muller, 'is seductive, because it organises and

simplifies knowledge. It offers numerical information that allows for easy comparison among people and institutions. But that simplification may lead to distortion, since making things comparable often means that they are stripped of their context, history, and meaning.’ ¹³²

Real life is complex, and when we single out certain aspects for measurement, we inescapably diminish the importance of all the others; and, if they do not become actually invisible, they come to be neglected. Muller notes:

When organisations committed to metrics wake up to this fact, they typically add more performance measures – which creates a cascade of data, data that becomes ever less useful, while gathering it sucks more and more time and resources ... Because belief in its efficacy seems to outlast evidence that it frequently doesn’t work, metric fixation has elements of a cult. Studies that demonstrate its lack of effectiveness are either ignored, or met with the assertion that what is needed is more data and better measurement. Metric fixation, which aspires to imitate science, too often resembles faith.’ ¹³³

Following procedures becomes a substitute for improving practice:

In situations where there are no real feasible solutions to a problem, the gathering and publication of performance data serves as a form of virtue signalling. There is no real progress to show, but the effort demonstrated in gathering and publicising the data satisfies a sense of moral earnestness. In lieu of real progress, the progress of measurement becomes a simulacrum of success ... ¹³⁴

The left hemisphere understands quantity better than quality. Its vision is comparatively simple. It strips elements away from context and history and is ignorant of their real meaning. When it is presented with evidence that what it is doing is not working, its invariable response is first to deny that there is a problem, but, if pushed, to respond *not* that we have done too much of something that is ineffective, but that we simply need to do *more* of it: because that’s what its theory dictates, and for the left hemisphere theory trumps reality.

As I have pointed out elsewhere, the left hemisphere tends to paranoia and control, not understanding the basis of the social phenomenon of trust, and desperate not to be vulnerable.

‘The demand for measured accountability and transparency waxes as trust wanes’, writes Muller. ‘There is an elective affinity between a democratic society with substantial social mobility and greater ethnic heterogeneity, and the culture of measured accountability ... The quest for numerical metrics of accountability is particularly attractive in cultures marked by low social trust.’¹³⁵

And of course its quest to transcend the vulnerability of human assessment and judgment does not succeed. As Gwyn Bevan and Christopher Hood, put it: ‘In the 2000s, governments in the UK, particularly in England, developed a system of governance of public services that combined targets with an element of terror. This has obvious parallels with the Soviet regime, which was initially successful but then collapsed.’¹³⁶ Professionals rely much more on intuition, which is anathema to managerialism. They see the human whole, which the managers don’t; and the more they are made to conform to managerial metrics, the more narrow their vision and practice becomes. Thus is killed the goose that laid the golden egg.

An obsession with counting, and accountability leads, here as elsewhere, to mediocrity. Here as elsewhere, we could learn from the wisdom traditions of the Orient. In Taoism, it is posited that only when the mind is free from pragmatic concerns, free for playfulness in thinking, and spontaneity in action, can there be creativity.¹³⁷ This is referred to as ‘uselessness’ – having no practical purpose in view. Creativity is not willed, and has no purpose. And of course what the left hemisphere particularly values is control and use: we require the right hemisphere to transcend such concerns.

COMMON SENSE

Dreyfus and Dreyfus refer to 'common sense', what is colloquially still known as *nous*. It is the ultimate embodied skill: something in which we all are, or all should be, experts. The existence of an equivalent to common sense exists across cultures, which does not mean that what is believed to be common sense in one culture will necessarily be so in another (although there is much common ground about essentials). Common sense can mean many things, and it is most vulnerable to criticism when it is used in the sense of folk science, eg, that the world is flat because it looks it. All the same it is, once again, not something we can afford to be without. The expression originates in the Latin *sensus communis*: the word 'common' here means something *shared* ('what we have in common'), not just *usual* ('spelling errors are common'). Intuitions evolve in our movement and engagement with the world and with one another, not in detachment and stasis. Common sense is the ultimate embodied skill that is acquired effortlessly through experience, and, to be effective, it needs to be protected from the gaze of analysis.

What on earth can I mean by that? Isn't that *exactly* what common sense needs to be subjected to? Well, obviously, in one sense of the word, yes; but in another sense, and less obviously, definitely not. Of course, I am not suggesting that we should allow common sense to subvert, or replace, science in any way. Science might, in fact – like religion – be *defined* as that part of the mental realm in which common sense does not apply. But it is a tragedy not to have it as a basis for our day-to-day experience of the world and of one another. And excessive analysis there destroys something of enormous value.

Einstein is full of common sense, yet it is he that wrote that common sense was 'the collection of prejudices acquired by age eighteen'. Absolutely correct. No good whatever to science, or for that matter to religion. But important for living a life. And with an almost uncanny accuracy Einstein points to the age of 18. Because it is around this point in life, precisely, that those who are never going to acquire common sense exhibit the fact most tragically. They become seriously ill and risk ending

their lives. Consider what happens in this well-known condition in which, most obviously, common sense is lost: schizophrenia.

Such a loss is perhaps the most invariable accompaniment of schizophrenia, something I touched on in Chapter 9, where I explored the experience of schizophrenia as an analogue of partial right hemisphere failure; in such patients, a return of common sense, like the return of a sense of humour, to some degree, if it can be procured, is a sign of recovery, at least from the acute psychotic phase. It is obvious that a loss of common sense can lead to delusional misinterpretations of experience. But it leads to much, much more than that – to a sort of cutting adrift of the soul from its moorings. What is lost is unreflective engagement with the world, the sense of a shared, unexamined reality. And a loss of the sense of *proportion*, which humour and common sense each imply.

The best exploration of this topic is acknowledged to be by the twentieth-century German psychiatrist and philosopher Wolfgang Blankenburg. In a paper entitled ‘First steps toward a psychopathology of common sense’, he demonstrated just how important to the proper functioning of a human being this lived, intuitive skill that we take for granted can be. ‘Borrowing from Goethe’s well-known formulation’, he writes:

one could say that common sense is an ‘organ’, which is formed in communication for the purpose of communication. It is formed in reciprocal interaction for the sake of this interaction.¹³⁸

Common sense, Blankenburg says, is content with uncertainty, with the probable, as the eighteenth-century philosopher Giambattista Vico had pointed out; whereas science seeks certainty. Schizophrenic subjects require certainty in those areas of life in which it cannot be had – those where, according to Blankenburg, ‘mere opinion (*doxa*) should prevail’;¹³⁹ we saw that one patient thought sex could be reduced to mathematics, another had to carry a dictionary strapped to his back. There is a considerable overlap between the phenomenology of schizophrenia and that of obsessive-compulsive disorder: the love of routine and familiarity, the intolerance of ambiguity, the need for certainty above all.¹⁴⁰ And with modern life, where

absurdity flourishes, while the common sense and a sense of humour that might have checked its advance have been howled down.

As we saw in Chapter 9, schizophrenic subjects replace *phronesis*, an approximate embodied understanding of the world, with *episteme*, a craving for certain abstract knowledge: there is in schizophrenia too great a detachment, an almost ‘scientific’ detachment, from the living world. Most of us live in a world that is semi-transparent, or, as one might say, ‘translucent’, in the sense that the eye rests temporarily on the surface, but does not stay there, instead passing through and beyond to something deeper and broader beneath, the nexus in which it is embedded, which gives it meaning. But in schizophrenia, the plane of focus has changed: the gaze stops short, the surface obtrudes and becomes opaque. Sensing that there must *be* meaning, but not being able to see, however coolly one stares at the object in front of one, what the meaning is, or wherein it lies, one jumps to a conclusion – that it is a hidden sign, a secret mechanism, perhaps something diabolical. Or that it has no meaning whatsoever, in a world composed of similarly senseless fragments. Meaning has slipped its berth and will sail off into space – or land on whatever happens to capture the eye.

Blankenburg quotes a 20 year-old female patient from his clinic in Freiburg:

What is it that I am missing? It is something so small, but strange, it is something so important. It is impossible to live without it. I find that I no longer have footing in the world. I have lost a hold in regard to the simplest, everyday things. It seems that I lack a natural understanding for what is matter of course and obvious to others.

She continues:

Every person knows how to behave, to take a direction, or to think something specific. The person’s taking action, humanity, ability to socialize ... all these involve rules that the person follows. I am not able to recognize what these rules are. I am missing the basics ... It just does not work for me ... Each thing builds on the next ... I don’t know what to call this ... It is not knowledge ... Every child

knows these things! It is the kind of thing you just get naturally ... It is just a matter of mere feeling, sensing what is appropriate. One has this from nature.¹⁴¹

Note a few things here. How vital and irreplaceable this intuitive sense that ‘every child knows’ is; how deep it is (‘I am missing the basics’), and how grievous the loss; how it is nothing so conscious as ‘knowledge’ that is missing; how this has to do with getting on with other human beings in the lived world; how she assumes there must be *rules* she does not recognise (such as the left hemisphere would understand); how everything seems to ‘build on the next’ sequentially, according to the programmatic rules she does not have (as the left hemisphere would have it), not forming a skein or network of multiply interconnected intuitive feelings derived from the context (as the right hemisphere would see it); and yet how she understands that others just have it ‘from nature’, a matter of feeling and *sensing* (such as the right hemisphere would understand, if only she could access it).

As Blankenburg puts it, it must be ‘a tacit possession, as the necessary prerequisite to accomplishing one’s daily tasks’. And the patient continues:

But I am missing something even more fundamental. These people do not even sense the necessity of common sense because they do not lack it. They simply *have* common sense. Then they are able to put two and two together. It is no longer so critical for them. They are able to create a connection with others and enter a realm in which everything functions from itself. Then, one is able to find a way. Then, it is natural and obvious. One is unable to live without it.

The poor patient in despair concludes: ‘Without it, one cannot manage at all!’¹⁴²

This is what it is like to have to examine everything, to find out the ‘rules’, to be conscious of what *must*, if it is to be preserved, remain tacit. Louis Sass calls it a loss of ‘ipseity’, that is to say ‘of-itself-ness’, the quality of grounding itself *in itself* without requiring further grounding. Without it there is no basis for understanding the rest of our reality: without it, one is in the realm of ‘turtles all the way down’.

It is the analogue of Cartesian scepticism. We come back to Merleau-Ponty: ‘the normal, non-pathological attitude consists in having confidence above and beyond what can be proved ... by means of the generosity of the *praxis*, by means of an action that proves itself in being carried out.’¹⁴³ Praxis: the embodied, active engagement with others that does not artificially create meaning, but is the condition *for* understanding the meaning; just as abstraction, detachment and disengagement, taken too far, lead directly to a failure of the means to understand, and ultimately to philosophical nihilism. And note the reference to generosity. When we act intuitively we are gracious and generous – more reflection makes us selfish and greedy.¹⁴⁴

Here let me quote Sri Aurobindo:

If the reason is not the sovereign master of our being nor even intended to be more than an *intermediary or minister* [an emissary], it cannot succeed in giving a perfect law to the other estates of the realm, although it may impose on them a temporary and imperfect order as a passage to a higher perfection. The rational or intellectual man is not the last and highest ideal of manhood, nor would a rational society be the last and highest expression of the possibilities of an aggregate human life, – unless indeed we give to this word, reason, a wider meaning than it now possesses and include in it the combined wisdom of all our powers of knowledge, those which stand below and above the understanding and logical mind as well as this strictly rational part of our nature. The spirit that manifests itself in man and dominates secretly the phases of his development, is greater and profounder than his intellect and drives towards a perfection that cannot be shut in by the arbitrary constructions of the human reason.¹⁴⁵

Eugène Minkowski saw that schizophrenia involved a lack of ‘vital contact with reality’, the pre-reflective attunement to, or immersion in, the world that grounds our being. He defined the vital contact as an ability to ‘resonate with the world’, to empathise with others, to intuit how to respond affectively and to act rightly, through our partaking in an intersubjective world:

Without ever being ever able to formulate it, we know what we have to do; and it is this that makes our activity infinitely supple, infinitely malleable, infinitely human – ‘human’ not in the sense ‘proper to man’ insofar as he is a member of the species animal but in the sense that envisages one of the supreme values, beyond which we would not be able to go.¹⁴⁶

The attempt to substitute rules for tacit knowledge is doomed to failure and a sign of psychopathology. Some reflections of the Dreyfuses on the nature of the law makes it clear why:

The law always strives for completeness but never achieves it. ‘Common law’ helps, for it is based more on precedents than on code. But the sheer number of lawyers in business tells us that it is impossible to banish ambiguity and judgment by specifying a code of law so complete that all situations are specified and prejudged. *Ceteris paribus* [‘other things being equal’] conditions and incompleteness are not merely annoyances showing analysis to be what Edmund Husserl, a philosophical precursor of AI, called an ‘infinite task’. Rather those problems point to something taken for granted: namely, a shared, human background that alone makes possible all rule-like activity. To explain our actions and our rules, we must eventually fall back on our everyday practices and simply say ‘this is what one does’ or ‘that’s what it is to be a human being’. Thus in the last analysis all intelligibility and all intelligent behaviour must hark back to our sense of what we *are*, which is, necessarily, on pain of regress, something we can never explicitly know.¹⁴⁷

Something of the same grounds our moral acts. If someone insists on reasons and rules, there comes a point where one has to say: ‘this is what it means to be a human being’. Virtue ethics, then, not utilitarianism.¹⁴⁸ There are certain things that, if I have to explain them to you, you will never get them at all.

CONCLUSION

Reason's progeny are abstraction, precision and linearity; intuition's progenitors are embodiment, the intrinsically imprecise, and complexity. Intuitions are of different kinds, but they are all subject to being discounted by a culture that relies overmuch on the left hemisphere's take. Once again, the more reliable of them appear to depend on right hemisphere function. They are due a degree of rehabilitation.

In a culture in which computation was not grossly over-prized, an experienced individual would function in almost every aspect of life according to embodied skills, unconscious reasoning, and intuition, with, of course, incursions of analytic thinking, but only when an obstacle was encountered. And the passing on of these skills, through shared experience, attention and imitation, would be the whole purpose of a culture and its traditions. In our culture, all mores have been abandoned; and what should remain implicit and in the realm of embodied skill is foregrounded as a 'problem' to be consciously solved – with the result that we grossly simplify and omit what is beyond calculation. I remind you of Whitehead's insight: 'civilization advances by extending the number of important operations which we can perform without thinking about them.'¹⁴⁹ The implication is clear: when it throws the process into reverse, and impels into the spotlight processes that should be going on in the background, it produces a sort of technically clever, but in reality ignorant, barbarism. Or something that seems very like a species of mental illness.

In Part I, I explored the hemisphere contributions to intuitive insight, making reference to the role played by it in the great discoveries of science and mathematics. In the next chapter I will look at intuitive insight as the most precious means we have to access truth about the world, across the board, itself both grounding and bringing to fruition the important work to be done by science and reason.

INTUITION, IMAGINATION AND THE UNVEILING OF THE WORLD

It cannot be too often repeated: from intuition one can pass on to analysis, but not from analysis to intuition.

—*Henri Bergson*¹

The imagination of nature is far, far greater than the imagination of man.

—*Richard Feynman*²

To the eyes of the man of imagination, nature is imagination itself.

—*William Blake*³

THE PRODUCT OF INTUITION IS INSIGHT. IT HAS BEEN DEFINED AS ‘ANY sudden comprehension, realisation, or problem solution that involves a reorganisation of the elements of a person’s mental representation of a stimulus, situation, or event to yield a non-obvious or non-dominant interpretation.’⁴ But there are other ways of describing where intuition takes us that may seem more in tune with what is actually experienced. We saw that Bergson called intuition ‘the *sympathy* by which one is transported into the interior of an object in order to coincide with what there is unique and consequently inexpressible in it.’ Bergson captures the idea of seeing

into the heart of things that the word ‘insight’ itself suggests, but goes beyond that to point out that what it finds there is inexpressible, an aspect of insight to which we shall return.

Insight is what intuition generates both in the world of everyday (as we saw in the example of Franck Mourier in the chapter before last) and in our attempts to understand, at a more fundamental level, the *nature* of the world. In both cases the insights it produces often surprise us: they can be, as the first definition put it, ‘non-obvious or non-dominant’. You could say they sometimes seem counterintuitive. As an ‘everyday’ example, consider this.

On 5 August 1949 firefighters were called to a canyon fire at Mann Gulch in Montana. The men parachuted in and were deployed on the other side of the canyon from the fire, but as they worked their way downwards, a gust of wind suddenly whipped the fire across to the side where they were stationed. As the fire began to spread rapidly up the hillside toward them, they ran upwards in an attempt to escape. Their team leader, Wag Dodge, however, realising that the fire was moving too fast for them to escape it, had a sudden insight. He lit a fire between himself and the advancing wall of flame, which burnt the ground bare, lay down in the burnt area, and waited for the fire to pass. He was almost the only survivor that day.

His insight was in one sense intuitive, in that it occurred to him in a flash without any conscious deliberation, yet it was also deeply counterintuitive in another sense: to fight fire with fire. It turns out that the Native Americans had discovered this strategy long before him, but Dodge had no knowledge of that fact. Intuition, then, is not conservative in the limiting sense of that word, that we are tied to the familiar. Although, as I discussed earlier, intuition delivers a form of common sense, a background sense of shared (and therefore conventional) understanding, without which neither we nor our society can flourish, it also explores – true to its origins in the right hemisphere – at times new, imaginative ways of looking at the familiar.

But intuition’s power to produce insights that are very far from obvious functions too in our efforts to understand in the most fundamental way the cosmos in which we live. Einstein’s theory of relativity is – or certainly was – deeply counterintuitive. And yet he relied on intuition to guide him there. ‘All great achievements of science must start from intuitive knowledge. I believe in intuition and inspiration’, wrote Einstein:

At times I feel certain I am right while not knowing the reason ... Imagination is more important than knowledge ... It is, strictly speaking, a real factor in scientific research.⁵

There is no mistaking the passion here. And how did Einstein think of intuition? What sort of a thing was he referring to?

He told the violinist Shinichi Suzuki that ‘the theory of relativity occurred to me by intuition, and music is the driving force behind this intuition’.⁶ Indeed, he said to the poet George Viereck ‘I often think in music’;⁷ and his sister Maja reported that when working on a problem he would play the piano, and then get up saying ‘there, now I’ve got it’.⁸ He is said to have told the psychologist Max Wertheimer that he never thought in logical symbols or mathematical equations, but in images, feelings, and musical architecture.⁹ He called mathematics ‘the poetry of logical ideas’, an ‘effort toward logical beauty’ in which ‘spiritual formulas are discovered necessary for the deeper penetration into the laws of nature.’¹⁰

Einstein is making several points here, it seems to me. That for him scientific and mathematical discovery involves intuition is clear; that the intuition uses shapes (‘musical’ or ‘architectural’) as metaphors for ideas; and is led on by a deep attraction towards beauty. The beauty was, certainly, bound up with logic – but not just with logic: it also involved feeling, and a sense of something spiritual.

He said a number of other things that reflect on the process of scientific or mathematical discovery:

the mind can proceed only so far upon what it knows and can prove. There comes a point where the mind takes a leap – call it intuition or what you will – and comes out upon a higher plane of knowledge, but can never prove how it got there. All great discoveries have involved such a leap.¹¹

This discontinuity, the necessity for a leap or sudden shift of thinking, is often mentioned by creative problem-solvers: and on another occasion Einstein wrote: ‘The supreme task of the physicist is to arrive at those universal elementary laws from which the cosmos can be built up by pure deduction. There is no logical path to these laws; only intuition, resting on

sympathetic understanding of experience, can reach them.’¹² This sounds as if it has much in common with the ‘pragmatic’ approach to truth I tried to articulate in an earlier chapter. In both the chapters on creativity and on science’s claims on truth, I have given numerous examples of scientists and mathematicians describing their discoveries as intuitive, every bit as much as those of poets and painters. As Gleiser puts it, ‘to go beyond the known, both Newton and Einstein had to take intellectual risks, making assumptions based on intuition and personal prejudice ... to a greater or lesser extent, every person engaged in the advancement of knowledge does the same.’¹³

Yet clearly maths and science do involve equations, chains of reasoning and verbal explanations. Those, however, must come later, according to Einstein, and are added after the fact: ‘Conventional words or other signs have to be sought for laboriously *only in a secondary stage*’, he wrote, ‘when the mentioned associative play is sufficiently established and can be reproduced at will.’¹⁴ Reaffirming that his thought was ‘visual and motor’, he continued: ‘in a stage when words intervene at all, they are, in my case, purely auditive, but they interfere only in a secondary stage as already mentioned ...’

Einstein did not always listen to his own advice. According to Freeman Dyson,

The great discoveries of Einstein’s earlier years were all based on direct physical intuition. Einstein’s later unified theories failed because they were only sets of equations without physical meaning.

¹⁵

What separates insight from analysis is that it is seen ‘at once’, not arrived at through a chain of distinct steps. By ‘at once’, I don’t mean ‘right away’, because the insight may take a very long time to incubate; it may well involve recasting the problem in a host of different ways over long periods. But, when it ‘hatches’, it is sudden, and it is, by all accounts, utterly convincing. Subliminal priming (cues of which we are unaware) can spark a later insight, after a considerable incubation period.¹⁶ William Wilson Morgan, who discovered the spiral structure of galaxies, did so while walking home one evening from the Yerkes Observatory, in what he

described as a ‘flash inspiration ... a creative intuitional burst’. He substantiated that moment’s insight with data that he presented at a conference a few months later. But that inspiration didn’t come from nowhere. Years of apparently ‘unsuccessful’ effort lay behind it, and were necessary to it. Necessary, mind you – but by no means *sufficient*. Interestingly, it was in the period of relaxation that followed concentrated effort, when the mind is elsewhere, that the insight came.¹⁷

Obviously just because an idea comes suddenly and seems utterly convincing does not mean that it is right. One day, while teaching in Graz, Kepler had an immediate and overwhelmingly convincing insight that the five Platonic solids contained the secret to the orbital paths of the then known planets. He felt ‘as though an oracle had spoken to him from heaven.’¹⁸ Alas, he was wrong.

Hao Wang, who was a pupil of Quine, an authority on Gödel, and Professor of Mathematical Logic and Applied Mathematics at Harvard (he also headed the logic research group at Rockefeller University, New York, for good measure) acknowledged that, of course, intuitive insights can be wrong, but insisted that intuition is indispensable in intellectual endeavour, just as much as in ordinary life:

There is no implication that intuition cannot make mistakes or that it cannot be improved by discipline or by the cooperative effort at advancing human experience. Hence, an appeal to intuition need not exclude, indeed to some extent often depends on, evidence from consensuses and pragmatic consequences ... When faced with an appeal to intuition, the natural response is not to reject it offhandedly on the ground of unclarity, but to ask oneself whether one does share the intuition and how strongly and detachably. In the ultimate sense *we have no absolutely certain knowledge at all, and a careful reliance on intuition is absolutely indispensable in daily life and in all intellectual pursuits*. There is no reason why, and indeed it is curious that, anybody should, only in doing philosophy, choose to dispense with explicit and conscious (public and private) appeals to intuitions.¹⁹

In fact, although intuitive insights are fallible, they may well be less so than other ways of apprehending truth. In a paper entitled 'Insight solutions are correct more often than analytic solutions',²⁰ Carola Salvi and colleagues build on earlier findings by the psychologist Janet Metcalfe. She had asked problem-solvers during a task to rate how 'warm' (close to a solution) they felt. The study threw up two interesting findings. The first was that those who solved analytically described gradually increasing 'warmth' during the task; but those who solved by insight remained 'cold' until the final 10 seconds before the solution (on that '10 seconds', remember that the brain shows signs of a problem having been solved about eight seconds before the insight dawns). And the second was that responses associated with sudden jumps in 'warmth' were correct more often than responses associated with incremental increases in 'warmth'. In other words intuitive solving had a higher success rate than analytic solving.²¹

INSIGHT: SHAPES, METAPHORS AND BEAUTY

Science and mathematics both attest to this intuitive form of understanding – and in the case of mathematics it is clearly the most important form of understanding. It happens not by going through intermediary steps, but by seeing the whole in a new way, and this often means seeing a visual image, certainly an analogy of some kind, similar to metaphorical understanding. So Anna Sfard, herself a mathematician, speaks of the mathematicians she recorded: ‘All the mathematicians I talked to said they just could not think without making pictures. All of them drew different shapes when trying to explain to me certain mathematical theorems or conjectures.’ And she continues:

When the abstract construct is supported by an image schema, the perception of its salient characteristics may become much more like our perception of the properties of physical bodies: it is immediate, it is holistic, and it is not mediated by a long chain of inferences. It is this ability to grasp ideas in a direct quasi-synthetic way, which, according to the mathematicians I talked to, gives them the feeling of ‘true’ understanding.²²

All the mathematicians she spoke to, she reports, talked of an image or metaphor: ‘The role of the metaphor of an object in this process cannot be overestimated’. One, for example, said:

To understand a new concept I must create an appropriate metaphor. A personification. Or a spatial metaphor. A metaphor of structure. Only then can I answer questions, solve problems ... without the metaphor I just can’t do it.

And once we find an answer, we remember what we perceived by insight better than anything we arrived at by more everyday means.²³

It may seem rather odd to non-mathematical readers that mathematicians should even talk about metaphor, let alone think it central

to the processes of mathematical insight. After all, we tend to think of metaphor as a purely linguistic concept, the standard ‘tool of the trade’ for poets and writers. But as I argued, both in *The Master and his Emissary* and in Chapter 15 above, metaphor is far, far more than that. It is fundamental to how we understand the world. It is only by seeing something as in some sense and however dimly ‘like’ something else that we build knowledge, and insight consists in perceiving likeness in dissimilar things. Poetic metaphor – describing one thing in terms usually associated with something quite different – is simply the most familiar use of metaphor and it is, of course, linguistic. But linguistic metaphor is, as it were, only a subset of a much broader mode of human perception which, as the mathematicians attest, includes what might be called non-linguistic metaphor. This broader conception of metaphor is central to insight. In his *De arte poetica*, Aristotle wrote about the role of metaphor and intuitive perception for poets, but he could have been writing about all those whose intuitive insights extend our knowledge of the world. He wrote: ‘the greatest thing by far is to be a master of metaphor. It is the one thing that cannot be learnt from others; it is also a sign of genius, since a good metaphor implies an intuitive perception of the similarity in dissimilars’.²⁴ In short, insight precipitates a new *Gestalt*.

That something of the same process is involved in mathematics and science as in poetry and art – the seeing of similarity within dissimilars – should not surprise us. They are all fundamentally creative processes, involving seeing patterns. As we saw in the testimony of Einstein, ‘seeing patterns’ took for him the form of images, feelings and musical architecture: it was certainly not linguistic and still less analytic: all that came later. To those of us who lack, or who have not been permitted to develop, this intuitive capacity to ‘see patterns’ and ultimately to be rewarded with sudden insight, what actually goes on may seem something of a mystery, as it does to a large extent to those who receive the insights. But they give us some clues. What draws them and what also seems to shape the patterns they see within the dissimilar is a sense of beauty. Mathematics, said Einstein, was an ‘effort toward logical beauty’.

He was not alone in thinking so. Anna Sfard again: ‘The role of aesthetic judgment in mathematical reasoning is a recurrent motif in mathematicians’ accounts of their own thinking.’ One of her subjects said:

Sometimes I make a certain ‘leap of thought’ only because I say to myself that in order for things to be beautiful they must behave in exactly this way and no other. It must be true this way, because otherwise it won’t be beautiful enough. I would even go so far as to say it wouldn’t be ethical if it wasn’t so.

The great French mathematician Jacques Hadamard, had a number of interesting observations to make on the process of invention in physics and mathematics after soliciting the views of over a hundred practitioners. ‘Invention is a choice’, he wrote: and ‘this choice is imperatively governed by the sense of scientific beauty’.²⁵ He later described the sense of beauty as ‘almost the only useful’ drive for mathematical discovery that exists.²⁶

Beauty is a test of correctness that many mathematicians, philosophers and scientists have experienced as a touchstone in their work. GH Hardy, in his *A Mathematician’s Apology*, wrote: ‘Beauty is the first test; there is no permanent place in the world for ugly mathematics.’ Similarly Henri Poincaré wrote that ‘the feeling of mathematical beauty, of the harmony of numbers and forms and of geometric elegance ... is a real aesthetic feeling that all true mathematicians know.’²⁷ According to Bertrand Russell, ‘mathematics, rightly viewed, possesses not only truth, but supreme beauty.’²⁸ Paul Dirac even pronounced, in relation to the discovery by Schrödinger of the wave equation: ‘It is more important to have beauty in one’s equations than to have them fit experiment’. This is because initially Schrödinger’s equation did not fit the data, given the state of knowledge at the time, and he lost heart: but once electron spin was discovered, it fitted the data perfectly. Schrödinger, according to Dirac, got this ‘very beautiful equation ... by pure thought, looking for some beautiful generalization of De Broglie’s ideas ... It seems that if one is working from the point of view of getting beauty in one’s equations, and if one has really a sound insight, one is on a sure line of progress’.²⁹

Again Poincaré sees the essential facts:

It is impossible to study the works of the great mathematicians, or even those of the lesser, without noticing and distinguishing two opposite tendencies, or rather two entirely different kinds of minds. The one sort are above all preoccupied with logic: to read their

works, one is tempted to believe they have advanced only step by step ... the other sort are guided by intuition and at the first stroke make quick but sometimes precarious conquests ...³⁰

Anna Sfard, too, comments that there seem to be two types of mathematicians. What she calls the *operational* types have ‘highly developed manipulative skills and use them as a principal means in their quest after meaning’. By contrast, for *structurally* minded mathematicians, having a metaphor ‘is the dominant need’:

... the manipulative skills, the ability to draw a systematic argument, are sometimes quite secondary ... The structuralists are more capable of direct-grasp understanding than those who think and understand in an operational way. This is probably why the belief that structural thinking is superior to operational was implicit in the opinions of the mathematicians I talked to.³¹

Vadim Krutetsky (or Krutetskii) who made a special study of gifted children, and mathematically gifted children in particular, concluded that the most able students strive ‘for the cleanest, simplest, shortest and thus most “elegant” path to the goal’, whereas average students pay little attention to the aesthetics of their solutions.³²

Even if we did not have the scientific evidence, each aspect of this would suggest a key role for the right hemisphere: its newness, its sensitivity to beauty, its presentation as a form rather than as a statement of any kind, its implicit nature, and its ability to allow something to ‘presence’, not merely to be represented. As Shelley so memorably said of the imagination:

it purges from our inward sight the film of familiarity which obscures from us the wonder of our being. It compels us to feel that which we perceive, and to imagine that which we know. It creates anew the universe, after it has been annihilated in our minds by the recurrence of impressions blunted by reiteration.³³
